How it came to be written is explained by Sir Wilson Jameson in a foreword. The Milk Industry Bill, one of the few really constructive legislative efforts of the decade before the War, was introduced in November 1938 and, by what many consider a grave error of judgment, was withdrawn after its first reading. Among a number of other measures the Bill gave local authorities permissive powers, subject to certain limitations, to make pasteurization compulsory in their areas. After its withdrawal, representations were made to the Ministers of Health and Agriculture in the hope that further legislative endeavours would be made to rescue the safety of the milk supply of Great Britain from the wreckage of the Bill. Though these representations were unsuccessful, they convinced the then Minister of Health, Mr. Walter Elliott, that there was need for the further education of opinion on the whole subject of pasteurization of milk in relation to public health. He asked Prof. Wilson to bring existing evidence together and review it, and this book, publication of which was considerably delayed by the outbreak of war, is the result.

As propaganda—and that in no sinister sense—it is successful and convincing. People who wish to retain anti-pasteurization beliefs as part of their religion are strongly advised not to read it. If they do they can scarcely avoid being persuaded of two things: first the need, from the point of view of national health, for efficient heat treatment of all commercial milk before it is consumed by human beings, and second, that pasteurization carried out by modern methods does not "rob milk of its essential elements" but has in truth a negligible effect on the milk's nutritive value.

One cannot help wondering, nevertheless, whether the book is not, now, knocking at a door already ajar. Even before the War the tumult and the shouting over pasteurization were dying, and the War itself has enabled a proper perspective to be achieved the more readily. The basis for the high emotional potential at which the pasteurization controversy, at its climax some fifteen years ago, was conducted was partly scientific, but to a much greater extent economic. The scientific world had, not very long before, been awakened to the essential part played by vitamins, particularly in the nutrition of the young, and to the fact that some of these factors were thermo-labile. Cow's milk was evidently one of their most important sources. Was not pasteurization, therefore, likely to diminish seriously the nutritive value of this vital food ? Was the alleged risk of disease and death—surely not a very serious one since very many drank raw milk but few seemed to suffer as a consequence—to be compared with the apparent certainty of loss of invaluable food factors as a result of heat treatment ?

Prof. Wilson collates and appraises existing data, and shows how serious is the first risk. His sombre statements as regards the extent of milk-borne disease cannot be far from the truth. As regards nutritive value, it has been clearly shown during the last seven or eight years that the effect of pasteurization on the vitamin content of milk, and on its nutritive value generally, is negligible. Prof. Wilson marshalls his evidence here very cogently, but quotes the several careful experiments begun about 1935 at the instance of the Milk Nutrition Committee (under the chairmanship of Lord Astor) on the feeding of comparable quantities of raw and pasteurized milk to children, to calves and to rats, as if they were just a number of sporadic and isolated investigations, whereas they were a planned and co-ordinated series which was designed to solve and, in fact, did solve, the question as to whether the commercial pasteurization of milk had any serious effect on the nutritive value of that milk.

A serious fear of those who opposed pasteurization so strenuously in the twenties and early thirties was that compulsory pasteurization—and none of us in peace-time likes anything compulsory—would increase the stranglehold of the large distributors on the producers of milk and would drive the producer-retailers out of business. There might have been some reason for this fear in the days before the advent of the Milk Marketing Board. Since that advent in 1935, the organized distributors have had to deal with an organization no less formidable than their own, and the economic argument against pasteurization has become far less intense. Nevertheless it is unlikely to disappear while producer-retailers exist who cannot pasteurize their milk before distribution. In such cases, is there to be a place for tuberculin-tested raw milk ? This question is at present of increasing quantitative importance, as the gallonage of milk retailed by producer-retailers has greatly increased since 1939.

The producer-retailer's case may be met after the War by the increased manufacture of small 'batch' pasteurizers that were being developed in the thirties to deal efficiently with fifty gallons of milk or even less. With the perfection of these plants—associated with a policy of partnership among the smaller producer-retailers to establish units of a reasonable economic size—the objective of the pasteurization of *all* milk for liquid consumption in Great Britain will be within technical range. Prof. Wilson says, "the need for pasteurization is fully justified by all the available scientific evidence and is supported by such a wealth of authoritative medical opinion as has seldom before been united in favour of any measure. . . ." He might without distortion have added "dairy scientific opinion", which has to consider, in addition to the medical aspects, other bearings of the pasteurization question.

H. D. Kay.

PSYCHOLOGY AND RELIGION

Psychology and Religious Truth

By Dr. Thomas Hywel Hughes. Pp. 160. (London : George Allen and Unwin, Ltd., 1942.) 7*s*. 6*d*. net.

In these lectures Dr. Hughes deals with some of the estimates of religion formed by psychologists. Freud's view that religion originates in the sex instinct is rejected by Dr. Hughes on the ground that this instinct is not itself fundamental but derivative from the will to live, which he regards as being the source of religion. He includes under this instinct not only the impulse to keep alive but also the wish to live well, for he takes the view that a spiritual no less than a biological need expresses itself in the will to live. Especially is this the case when a self-conscious stage has been reached. Also, religion arises from and gives expression to the whole personality and not just to a part, for example, the sexual. The view associated with the names of Durkheim and Levy Bruhl, that religion originated in the herd instinct, is also rejected. According to Levy Bruhl, the conception of God is in reality nothing but the idea of society or social cohesion, as it finds its unity in strong emotion. The decisive objection to this theory, in Dr. Hughes's opinion, is the fact that religion is an intensely individual and personal matter, and however far back we go, we find that religion begins in single souls who initiate the social movements in religion.

Some psychologists, of whom Leuba and Freud are examples, have taken the view that the idea of God is an illusion due to two familiar mental processes, projection and regression. The human mind projects and personalizes its own private feelings and desires, and often gives its projections content and meaning by clothing them in a garb of early memories and experiences. But Dr. Hughes points out that this process of mental projection is not necessarily a form of self-deception. Some of the principles upon which all our scientific knowledge is based are such projections ; for example, the principle of the unity and uniformity of Nature. Nature itself as it appears to the observer is far from being a unity, but the scientific inquirer projects into Nature his own consciousness of personal unity. Just as he is himself the integrating bond which links into one whole all his diverse experiences, so he projects upon the diversity of Nature a similar principle of unity. It by no means follows that such a procedure is illegitimate ; on the contrary, it has proved highly fruitful in results, and has enabled Nature to be reduced to order and understood. A similar projection is the idea of causation, which projects on to Nature man's consciousness of initiating action. From the mere observation of Nature only a succession of events is discernible, as Hume pointed out ; the idea of causation is a projection of the human mind, which is justified by results.

Dr. Hughes also examines Leuba's estimate of religious experience as of like nature with the experiences resulting from drugs, alcohol, or some pathological state. That some mystical states are subjective and induced by drugs or other similar means does not warrant the conclusion that all mystical states are illusory. One might argue that the illusory nature of the snakes observed with so much distinctness by the sufferer from delirium tremens proves that all snakes are illusory. Moreover, the effects of genuine religious experience are very different from those induced by opium or gin; they strengthen and enrich the character, bestowing upon the individual the capacity to endure the heaviest strains, mental, moral and physical. The prophetic utterance, "And a little one shall become a thousand", has come true often enough in the history of religion, which can release hidden potentialities to a surprising extent.

In opposition to the Behaviourists, Dr. Hughes is confident that "a psychology with a soul" is now in the ascendant, "perhaps more so than at any time since the beginning of modern philosophy in Descartes". He holds that this is largely due to the psycho-analytic school, who have put the *psyche* with its moods and energies at the centre of their teaching. One of the great gains to psychology from the new psychology, in his view, has been that it has rid the study of the predominantly material and physiological bias so long associated with it. He observes that the problem of the relationship between body and mind is by no means settled; he does not refer to Sir Charles Sherrington's recent pronouncement as to the impossibility of reducing mind to terms of energy. But he expresses the opinion that "the trend of psychological thought is towards regarding the idea of a future life as at least probable".

Dr. Hughes also has interesting chapters on the bearings of psychology upon certain specific Christian doctrines, such as the Trinity, the Atonement, and the Person of Christ. The discussion of the doctrine of the Atonement will perhaps be of most interest to psychologists, as facts of human nature are primarily concerned. Dr. Hughes observes that Freud "has revived the conception of original sin, and even afforded some support to the idea of total depravity". Another point is the distinction drawn by modern psychology between sin and moral disease, which has made it easier to deal with certain weaknesses of character. On the other hand, it is important to realize that sin is always a matter of the will and implies personal responsibility. The notion of moral disease may easily be led to 'cover a multitude of sins' to the doubtful advantage of the patient. We could wish that while dealing with this topic Dr. Hughes could have devoted some space to an examination and evaluation of the Pauline psychology of 'spirit' and 'flesh' which is certainly out of date, and which gravely affects the efficiency of the attempts of the Christian church to give guidance on certain moral problems. One feels that if one is to equate the 'flesh' with the 'libido', it must be the source of much that is of value as well as of some things less attractive. But perhaps Dr. Hughes will deal with this and other similarly interesting questions, among which we should include the body-mind problem, in another series of lectures. Meanwhile he deserves our thanks for a very useful piece of work.

J. C. HARDWICK.

BIOCHEMISTRY—GENERAL AND PARTICULAR

Annual Review of Biochemistry

James Murray Luck, Editor; James H. C. Smith, Associate Editor. Vol. 11. Pp. ix+736. (Stanford University P.O., Calif.: Annual Reviews, Inc.; London: H. K. Lewis and Co., Ltd., 1942.) 5 dollars.

HERE we have a volume of more than 700 pages with scarcely a mention of war; there has been little diminution in the scientific production of the free peoples. It is indeed refreshing to escape into such an oasis of progress, away from the constant repetition of war news and war aims which assails us on the air and in every form of printed literature—newspaper, journal and novel.

The editor reminds us that these reviews now enter their second decade, and that they started in a period when great scientific activity was independent of severe economic depression. What a lot they have had to chronicle, what a storehouse of information for him minded to produce a book on a decade of progress! We had begun to write that the sciences covered by the elastic term biochemistry had surpassed all others in the rate of advance when we remembered that in physics the same applies.

The world to-day is largely science-conscious; the spread of education and the provision of educational facilities have borne fruit. The trained men are there, keen in their generation; the spores of new conceptions are found in the atmosphere of any college. New methods of experimentation make for quicker results, easy publication brings them quickly to the cynosure of the critical. Each step forward by one opens up the way to new advances by many. There is no prostitution of science to evil ends, for surely the man of science is free to defend his freedom with all likely weapons at hand. It is as noble to discover something of use to humanity, to alleviate sickness as to investigate something of no use to anybody. It is true that one never knows when the purely theoretical may turn up trumps, as when Lord Rayleigh's weighing of nitrogen led to the discovery of the rare gases; but this did not become less meritorious because it led to such an advance in electric lighting.

The answer is plain: let the scientific man go his own way, following his inclinations to understand and to discover; endeavour shall be his watchword. Let there be more laboratory facilities, more scholarships, more books; then the world will glean the kindly fruits of science.

There are twenty-six topics this time in the "Annual Review of Biochemistry", with many new names among the authors. The treatment varies according to the suitability of the subject for review; that is, whether it can be summarized to definite conclusions.

An interesting section is that on lignin, by Harold Hibbert, who has done so much for cellulose chemistry at McGill. The molecule is a complex one and is now held to contain propylphenol units, the union being of a carbon to carbon type involving oxygen ring formation between side chains and aromatic nuclei. The mechanism of the synthesis of phenols in the plant is also discussed: these are apparently synthesized in both the lower and higher forms of plant-life to function as hydrogen transportation, respiratory catalysts. In the higher plants, such catalysts eventually undergo a complex series of changes to yield lignins.

The sterols are much to the fore; one review by C. W. Shopper, of Leeds, summarizes recent work on the steroid sapogenins, the cardiac glycosides and the toad poisons; another on hormones, by J. J. Pfiffner and O. Kamm, of Detroit, emphasizes in particular that relationship of structure to physiological action which is a perennial field of inquiry by chemists.

Biochemistry is advancing from the general to the particular. For example, W. D. Armstrong devotes twenty pages to the teeth under the heading of constitution and properties of dental tissues; Selig Hecht, in thirty pages, describes the chemistry of visual substances, largely the visual purple, regarded as a conjugated protein.

A reviewer can do no more than cite a few headings, avoiding the temptation to dwell on those subjects which have most appeal to him; there comes the reflection, if we only had time to read and try to master the whole. For this is what our medical advisers have to do in the future, though by then it will be presented in potted and tablet form for easy assimilation. One thing is certain, in ten years time there will be as much as ever to discover, even though all we know to-day will then appear as but the foundations of knowledge. Yet some compounds still refuse to give up their secrets: sugar, for example, has not yet been made in the laboratory.

E. F. ARMSTRONG.

SOCIOLOGY AS AN ACADEMIC DISCIPLINE

An Introduction to Sociology

By Prof. John Lewis Gillin and Prof. John Philip Gillin. Pp. viii+806. (New York: The Macmillan Company, 1942.) 18*s*. net.

SOCIOLOGY is achieving maturity as a discipline. Its increased recognition in American as distinct from most British universities is indicated by the appearance of university text-books. Whether as a subject it is in any way distinguishable from political science is a reasonable matter of doubt, depending upon whether we understand politics as Aristotle did or as something to do with politicians.

Messrs. Gillin and Gillin omit to note that the State is a modern phenomenon and that political science can scarcely be, and in fact is not, limited to study of it. They do not discriminate here between scientific and popular usage. Aristotle knew nothing like the modern State and begins with discussion of the family. It is not an issue discussed in the present volume. This overlooking of studies in political science, in the traditional acceptation of that word, deprives the book of some of the interest which it might possess, and could with advantage be remedied in a later edition.

Here we have a straightforward text-book of highly commendable lucidity, comprising chapters on population, culture, kinship groups, political constitutions, religious constitutions, social change, delinquency and crime. Some of the 'exercises' appended to the chapters raise interesting questions in the minds of those of us who recall that, for example, Prof. Laski holds (to my mind wrongly) that history and the social sciences cannot be 'objective'. For example, one 'exercise' reads: "What biases would you have to beware of if you set out to study scientifically fascism? Democracy?" What biases, one wonders, would Profs. Gillin have to beware of? Or Mr. Bernard Shaw? Or the professors of the Marx-Lenin Institute, Moscow?

Owing to the vast field covered, accuracy rather than novelty is aimed at, and the chief significance of this book, for any reader who is not a class student, is that it shows what is the shape increasingly being assumed by this subject in the ordinary teaching curriculum of two distinguished universities. It provides an admirable 'orientation' and general background for more specific studies. Discussions of methodology are reduced to one chapter. But the student who asks for an adventure of ideas in social questions will here find stimulus, and the student perplexed by issues of 'race theory', moral evolution, economic security and the like will be given perspective. As such a guide this manual will doubtless perform a very useful purpose.

GEORGE CATLIN.

PSYCHOLOGY OF WAR AND PEACE

War and the Psychological Conditions of Peace

By Dr. William Brown. A second and enlarged edition of the author's "War and Peace". Pp. viii+144. (London: Adam and Charles Black, Ltd., 1942.) 7*s*. 6*d*. net.

DR. WM. BROWN'S volume "War and Peace: Essays in Psychological Analysis" appeared in 1939, and now re-appears in a new edition with a new title. Three new chapters are added, the size of the book being thus increased by about a half. As the earlier chapters were written before the outbreak of war, and the later ones since that event, the reader has an interesting opportunity of seeing how well the author's estimate of the Nazi psychology has been borne out during the last three years. Dr. Brown's qualifications for writing such a book are unique. He has known Germany from his student days, and has kept his knowledge well up to date ever since; he is eminent in the fields of experimental psychology and psychiatry; he gained close knowledge of the psychology of the fighting man in the War of 1914–18 during his four years of active service; and he has taken the utmost pains to understand the mysterious Hitler and his hold upon the German people.

Steering clear of propaganda, and speaking only as a psychologist, Dr. Brown regards Hitler as cunning and clever, but "held firmly in the grip of his paranoid nature". To say that Hitler is only a figurehead is to under-estimate his importance as not only the creator but also the creation of his followers, whose nature is such that it dovetails into his. That there are plenty of Germans who will work for world-peace after the War Dr. Brown is convinced. Meantime the position is full of peril, and when Germany has been defeated and punished she will need re-education, in which process many highly cultured Germans of the older generation will take part honestly and thoroughly.

The general reader will find little difficulty in following the author's argument, but it may be suggested that he will do well to make some preliminary study of paranoia and paranoid tendencies in one of the best treatises on abnormal psychology. Dr. Brown's note at the end of his fifth chapter will be found helpful.

RUTHERFORD: LIFE AND WORK TO THE YEAR 1919

By PROF. H. R. ROBINSON, F.R.S.*
Queen Mary College (University of London)

"I AM sure that we all ought to . . . give some of our recollections of those past and gone before they are lost for good."

These words, written by Rutherford himself in a letter to Rayleigh (March 1936), may well serve as my text. There are in existence excellent biographies of Rutherford, as well as obituary notices in many scientific and other journals; it will therefore be unnecessary for me to attempt to give a connected account of the first forty-eight years of Rutherford's life. I shall try to mention the more salient facts, though I shall necessarily be restricted to a bare minimum of detail, but I want above all to convey, so far as I can, some impression of the atmosphere of proud and contented endeavour and achievement which he maintained in his laboratories in Manchester. I do not under-estimate the difficulty of this; Rutherford has filled so much of my mental horizon ever since I became his pupil in 1908, that I can scarcely expect to see everything concerning him in a perspective which others would necessarily recognize as true, but I will try to do it.

Fortunately, though Rutherford's genius was of a most uncommon kind, and his character and outlook difficult to assess, we have, in addition to personal recollections, one extremely valuable source of information; mainly through Lady Rutherford's care and forethought, a great part of Rutherford's correspondence has been preserved and filed. We have, therefore, expressed in Rutherford's clear and vigorous English, much first-hand information that would otherwise have been lost to us.

Rutherford's paternal grandfather, George Rutherford, a wheelwright, left Scotland in 1842 to settle, with his family, in New Zealand. His son James, born in 1839, married in 1866 Martha Thompson, who had come to New Zealand at the age of twelve, and who for a short time before her marriage worked as a school teacher. Ernest Rutherford, born on August 30, 1871, was the fourth of the twelve children born of this marriage. He was born at Brightwater (Spring Grove), not far from Nelson; four years later the family moved to Foxhill, and in 1882 to Havelock, both in the neighbourhood of Nelson. Ernest attended the State primary schools at Foxhill and Havelock, and apparently was very well taught at both schools. In 1886 he won a scholarship which took him to Nelson College, and at about the same time his family moved to Pungarehu, in North Island—not very far away—where his father, who had previously worked as a wheelwright, farmer, timber contractor and engineer, now concentrated on large-scale flax production.

Nelson College was evidently a model establishment, with an excellent headmaster in W. J. Ford and a fine mathematical master in Dr. W. S. Littlejohn, who gave Rutherford a sound start in mathematics and physics. Rutherford had a very successful three years in Nelson, winning awards not only in his best subject, mathematics, but also in Latin, French, English literature, history, physics and chemistry. It is on record that in June 1888 he was top of the sixth form in *all* subjects.

In 1889 he won a junior university scholarship which took him to Canterbury College, Christchurch, where he had again a continuous record of academic success. It was in Christchurch that he met, and became deeply attached to, Mary Newton, who became his wife in 1900.

Rutherford did his first research work—on the magnetization of iron in rapidly alternating fields—in a draughty cellar of Bickerton's laboratory at Christchurch, and later he developed an ingenious magnetic detector of electromagnetic waves. This work, which would have been remarkable enough as the first performance of a young researcher under the most favourable conditions, must rank even higher when we think of the circumstances in which it was done.

In 1895 the award of an 1851 Exhibition Science Scholarship enabled Rutherford to move to a great centre of research, and he elected to go to Cambridge—beating J. S. Townsend by a short head for the distinction of being the first research student to enrol under J. J. Thomson for the research degree newly instituted in Cambridge for workers from other universities. We find soon afterwards, in a letter to Mary Newton (October 3, 1895), "I am very glad I came to Cambridge. I admire Thomson quite as much as I thought I would, which is saying a good deal."

Here he continued work on Hertzian waves with his magnetic detector, and had notable successes in detecting waves at—for the time—great distances from their source. He soon, however (Easter 1896), dropped this to work with Thomson on the new subject of ions in gases, building up in a remarkably short time a very complete theory of gaseous conduction and determining experimentally many of the characteristic properties of the ions. From this work, by an entirely natural transition, he passed to the study of the recently discovered Becquerel rays, thereby finding his true life's work—radioactivity.

Here we may with advantage pause to recall the state of atomic physics at the time of Rutherford's first Cambridge period. It was one of almost unparalleled activity. In November 1895, Röntgen discovered X-rays, largely by accident. Becquerel's discovery of radioactivity in February 1896 was largely a second accident arising out of Röntgen's discovery. It was, of course, the use of X-ray tubes as sources of ionization that made possible Rutherford's work on gaseous conduction.

About the same time Lorentz, the great pioneer of electron theory, was able to show that the newly discovered Zeeman spectral effect could be quantitatively explained by the assumption that spectral lines were the result of radiation by charged particles the specific charge of which was of the order of a thousand times that of the hydrogen ion in electrolysis. The electron, possessing this property, was isolated by J. J. Thomson in 1897, and shown to be a constituent of all ordinary matter—and this may be taken as the starting point of the modern electrical theory of the atom. The charge of the electron was measured soon afterwards by Townsend, Thomson and others; another essential link in the chain of discovery was Townsend's brilliant work on the diffusion of gaseous ions, which proved beyond doubt that the charge of a normal gaseous ion was identical in magnitude with that of a monovalent electrolytic ion.

---

* From the first Rutherford Memorial Lecture of the Physical Society, delivered on November 6.

To some extent, therefore, Rutherford's entry into radioactivity and atomic physics was an accident of time and place—but this is the last occasion on which we can speak of any element of chance in his life's work. From this time on, he made and pursued his own line, and it would scarcely be an exaggeration to say that his subsequent achievement would have been little less imposing or significant if, in the whole period with which we are concerned, he had been completely oblivious to everything that went on outside his own mind and his own laboratory.

In 1898, when in full career, Rutherford made the difficult decision to leave Cambridge for the Macdonald research professorship of physics at McGill University, Montreal. Rutherford's estimate of himself at this time (which was clearly much less high than that which Thomson had formed) is quaintly expressed in a letter to Mary Newton. "It sounds rather comic to myself", he says, "to have to supervise the research of other men, but I hope I will get along all right." To anyone with the least knowledge of Rutherford's career, it must seem more than "rather comic" that Rutherford should have harboured such doubts. Even much later still, with an immensely fruitful period behind him, he showed himself inordinately gratified that foreigners like Hahn and Godlewski should think it worth while to go over to Canada to work with him.

The outstanding advance made in the McGill period was the development of the disintegration theory of radioactivity, first advanced by Rutherford and Soddy in 1903. By the time Rutherford left Montreal for Manchester, in 1907, this theory had been established beyond all reasonable doubt, and many of the details of the sequence of transformations had been elucidated. Rutherford had fully established, in his own mind at least, the nature of the alpha particles and had made rough measurements of their velocities and specific charge. He had also measured, with Barnes, a number of heating effects. His fame was now securely established, and he made of his laboratory what its founder had always hoped it would become, a permanent centre of research in Montreal. Higher education in Canada owes much to Rutherford—an indebtedness which has been generously and repeatedly acknowledged. On his side, Rutherford was at least equally ready to point out that the benefits of his association with Canada were by no means one-sided.

Rutherford's invitation to Manchester was largely due to the foresight of Arthur Schuster, who had marked him down some time before as the successor he would wish to see in the Langworthy chair of physics. Schuster was, for a physicist, a wealthy man—a fact on which Rutherford commented naïvely in a letter to his mother soon after his arrival in Manchester. He was, moreover, like so many of his race, not only generous, but also generous with rare discrimination, and when he retired to make way for Rutherford, he endowed, out of his own pocket, a readership in mathematical physics—the one thing needed to complete the strength of the department. The Manchester laboratory was, for its time, well designed and equipped, and could produce adequate supplies of liquid air. It was less well fitted than McGill for radioactive research, but Rutherford was never a stickler for luxury in working materials, and Feather has recorded in his biography that on June 6, 1907—less than three weeks after leaving Montreal—he was setting up an emanation electroscope in his new laboratory.

He was lucky in the men he found in the Manchester laboratory, most of whom turned over to work in radioactivity. He was perhaps most fortunate in finding Hans Geiger, a young graduate of Erlangen who had already done research under Schuster, and William Kay, a young mechanic who soon afterwards became head steward of the laboratories. To Kay, who surely ranks high among the world's greatest laboratory stewards, must go the credit for much of the smooth running of the laboratory.

Geiger was a well-trained and capable all-round physicist, with a considerable command of experimental technique, and his enthusiastic collaboration proved invaluable to Rutherford from the outset. Rutherford and Geiger's electrical counting of alpha particles—an amazing technical feat in those days—was completed within a few months of Rutherford's arrival, and the paper was read before the Royal Society in June 1908, with that on the total charge carried by the particles.

An acute shortage of radioactive material in the laboratory, which faced Rutherford on his arrival, was soon relieved by a generous loan of 450 mgm. of radium bromide made to him by the Vienna Academy. Shortage of apparatus became rather serious as the work of the laboratory rapidly expanded, but no doubt Rutherford at this stage in his career had no difficulty in tapping a number of sources for research funds. Dr. Norman Smith, Registrar of the University of Manchester, has been kind enough to get for me the details of the annual grants made for apparatus and equipment to the Physics Department throughout Rutherford's tenure of the chair. For the pre-war years, these (excluding amounts earmarked for electrotechnics) averaged less than £420 a year, and in 1915–19 they dropped far below this figure. With these grants Rutherford worked wonders, and there can be few instances in the history of science of comparably rich yields from such modest investments.

Rutherford attracted to Manchester many experienced workers from other universities, and by now he had learnt to see nothing abnormal in this. He was so full of ideas for work that he needed every man he could get, and he trained as many as possible of his own students for research—it being quite usual for an undergraduate to begin on a selected problem in his third year at the University. Geiger, appointed research assistant, took over much of the training in radioactive measurements, and the training course was substantially that described in Makower and Geiger's "Practical Measurements in Radioactivity", published in 1912.

Rutherford's most fruitful contribution to general atomic physics arose directly out of the results of an experimental problem which had been given to Ernest Marsden, one of the first of the Manchester trainees. This was the work on large-angle α-particle scattering, carried out mainly by Geiger and Marsden in collaboration. As Rutherford put it many years later, "I told Geiger that young Marsden should begin a research. Why not let him see if any α-particles can be scattered through a large angle ? I did not believe that they would be. . . . It was quite the most incredible event that has ever happened to me in my life. It was almost as incredible as if you fired a 15-inch shell at a piece of tissue-paper and it came back and hit you" ("Background to Modern Science" (1938)). Thus originated Rutherford's nuclear theory of the atom, which he worked out in masterly fashion in 1911, and which changed the whole face of modern physics. The picture of the atom was completed by Bohr who, after working for some months in Rutherford's laboratory, first applied new quantum principles to the electrons of the nuclear atom, and by Moseley's brilliant work on the X-ray spectra of the elements, begun in Manchester in 1913.

It was characteristic of Rutherford that, though his research school was almost completely dispersed by the War of 1914–18, and though his time was so fully taken up by work of national importance at home and abroad, he should have contrived during those years to carry through successfully yet another epoch-making research. In experiments which he began in 1917 and ended early in 1919, generally with Kay alone to help in setting up apparatus and counting scintillations, he succeeded in showing that the nitrogen nucleus could be disrupted by the impact of a swift α-particle, with the emission of a hydrogen nucleus. This, the first detected example of 'artificial transmutation', was the last work he published from Manchester; its further development belongs to the second Cambridge period.

When I, as a young student, first met Rutherford in 1908, he was at the height of his powers—as he had indeed been for many years and as he remained right to the end of his life. I am sorry that I was not one of that generation of students of whom Rutherford wrote to Boltwood in October 1907, that "I find the students here regard a full professor as little short of Lord God Almighty". I can, however, testify that this was how Rutherford was regarded by the men of my year and those who followed us, though he was mistaken in believing—if he really did believe—that all full professors were objects of reverence to their students.

Officially, honours students had no lectures from the professor in their first year, but in practice we used regularly to attend his elementary lectures, partly because they were really illuminating, whatever their topic, and partly for the beautiful, and often sensational, experiments which Kay prepared for them. It seemed at times that it was Kay's taste in lecture demonstrations that really dictated the course of a lecture, and sometimes—not often—Kay was called upon to act as prompter, in response to appeals in which Rutherford presumably believed that he had reduced his normally huge voice to a scarcely audible whisper.

We also at times saw Rutherford walking along the corridors, singing lustily a tune recognizable as a rendering of "Onward, Christian Soldiers", and later we knew this to be a sign that research was going particularly well. I was interested to learn many years later, from an article by Prof. Norman Shaw, that this, I believe quite unconscious, habit dated from the McGill period. In less favourable times there was a melancholy dirge which no one ever identified—partly because, for obvious reasons, it was considered tactful to let him have the corridor to himself on these occasions, which were fortunately very rare.

We saw Rutherford in his most inspiring form at the physics colloquium, which met on Friday afternoons, the meetings being preceded by an enormous tea-party at which Lady Rutherford generally presided. Rutherford always addressed the first meeting of the session, giving with obvious enjoyment a summary of the main work done in the laboratory during the preceding session. The attendances were large, as many of the chemists and mathematicians came over to hear Rutherford, and in the atmosphere of sustained enthusiasm which he created, no young student could fail to feel that he was highly privileged to be of that community. I think we all felt then that we were living very near the centre of the scientific universe, and maturer reflection has only served to convince me more strongly that we were right. This sense of privilege naturally grew stronger in those who went on to do research, even in those of us who were doing relatively humble tasks and not, like Moseley, the things that were going to matter fundamentally for years to come.

I should like to state some of the more obvious reasons for Rutherford's extraordinary power as a leader of research. First, of course, there was his own unique and apparently almost intuitive grasp of the essentials of a problem. Next, his interest in the course of an investigation and his impatience to know the result were so passionate that they inevitably infected even the laziest of his co-workers. Then there was his incorrigible friendliness to even the least worthy of his research men; a man who is invited regularly to Sunday supper at his professor's house, who meets him nearly every day across the laboratory tea-table, who is generally treated as the social equal of an emeritus professor, and who is constantly and pointedly asked how his work is getting on, is likely to do more and better work than one who is left to feel that nobody wants him or his results very much. No doubt Rutherford's friendliness was partly due to his upbringing in New Zealand, and enhanced by nine years of life in Canada; no one who has seen much of New Zealanders in the mass can have failed to recognize that they are an unusually friendly and companionable people. Rutherford had these qualities in an extraordinarily high degree, and they undoubtedly helped to keep things going in the laboratory.

I would emphasize, too, in this connexion Rutherford's obvious and enormous delight in experimentation. I remember once, after he and I had wasted the whole of a fine Saturday afternoon in a quite ineffectual attempt to purify a very dirty little sample of radon with which we had hoped to work, Rutherford's saying with obvious sincerity, as he sucked contentedly at his pipe, "Robinson, you know, I *am* sorry for the poor fellows that haven't got labs. to work in!" It is not really surprising that in such an atmosphere a man like Andrade, arriving fresh from work on ionization in flames and from the making of metallic single crystals, should have found himself in next to no time working on gamma-rays, or that Darwin, the second of the Schuster Readers, coming under contract as a mathematician, should have suddenly found himself involved with gold-leaf electroscopes and an experiment on a branching radioactive series.

This lecture began with a quotation from Rutherford. It may fittingly end with a quotation from von Helmholtz, part of an address given sixty years, almost to the day, before the death of Rutherford. Von Helmholtz was speaking of his own great teacher, Johannes Müller, and after referring to the student's need for "daily mental intercourse with teachers from whom he learns something of the workings of the thoughts of independent minds", he goes on to say, "Anyone who has once come in contact with one or more men of the first rank must have had his whole mental standard* altered for the rest of his life".

RECOVERY OF METALS FROM SCRAP*

By SIR HAROLD HARTLEY, C.B.E., F.R.S.

THE dominant feature of industrial development in the nineteenth century was the use of power, but closely associated with it and of scarcely less importance was the enormous increase in the use of metals made possible by metallurgical progress. In 1800, for example, the world production of iron and steel was about half a million tons; in 1900 it was forty million tons, and now is more than three times as great. This rapid growth in the use of metals made serious inroads into the world reserves of ores, and in some countries the available resources, particularly of the richest ores, were exhausted or seriously depleted; so that the problem of conservation has become urgent, and with this lies a close connexion with the question of the ultimate fate of metals in use and their recovery as scrap. To what extent are they lost in use? Do they, in fact, follow man-made cycles like the well-known carbon and nitrogen cycles in Nature, so that the world stock is not in fact depleted?

Unavoidable losses in the use of metals or alloys due to wear, corrosion, heat and dispersal dissipate them so that they cannot be recovered; similarly, their use in chemical compounds such as pigments tends as a rule to total loss. The only examples of metals in which there is little such wastage apart from their use in plating or in thin films are the so-called precious metals, gold, silver and the platinum group. An exact study of the fate of the industrial metals is impossible owing to the lack of accurate statistics and to the uncertainty as to their secondary uses, but it is clear that in this century scrap is playing an increasingly large part in metal production and must enter into any comprehensive survey of world metal supplies in the future.

In the United States, for example, it is estimated that in recent years (1929–38) ferrous scrap has amounted to 75 per cent of the output of steel, while non-ferrous scrap has accounted for 50, 45 and 35 per cent of the total domestic consumption in all forms of copper, lead and aluminium respectively.

Each metal presents a different problem according to its nature and uses, but there are certain general aspects to be considered first in order to clarify so far as possible a somewhat confused picture.

Definition of Scrap

The word 'scrap' is used here to cover what are often described as secondary, reclaimed or runaround metals. Obviously there are different types of scrap which may be defined to indicate their origin as:

1. *Process scrap.* Scrap arising in the production of a finished or semi-finished article which is re-used in the plants of origin. This includes ingot heads, gates and risers from castings, crop ends of rolled material, trimmings from sheets, tubes, etc., all of which are normally returned to the melting furnaces in the same works.

2. *Engineering scrap.* Scrap such as swarf, drillings, turnings and rejects produced in engineering shops which are usually separated from the primary production, so that this scrap cannot be so quickly absorbed. Further, its physical character and high degree of oxidation often make it difficult to use in re-melting furnaces.

3. *Old scrap.* This consists of disused material arising from obsolescence, accident and worn-out parts. Recovery of this is a skilled trade involving the breaking-up of machinery into its component scrap categories; for example, a motor-car is stated to contain no less than twenty-five different ferrous alloys and the same number of non-ferrous alloys.

It is, of course, impossible to make hard and fast distinctions between these three classes, particularly between 1 and 2, but these two classes cover new scrap, metal that has not been in service, as distinct from 3. Scrap of classes 2 and 3 may, however, easily get mixed in the process of collection before it reaches the producer again.

Disposal of Scrap

The disposal of scrap metals and their use to the best advantage is becoming more complicated each year owing to the increasing use of alloys. The whole problem would be vastly simpler if metals were used mainly in a pure state, or admixed in the case of iron with carbon alone. In many cases, for example bearing metals and tool steels, the alloys are kept separately in the process of collection for re-use after re-melting and adjustment of their composition, as the recovery of the constituent metals from their alloys would be a wasteful and often a difficult and uneconomical operation. The sorting and classification of scrap is therefore a matter of great importance. For process scrap it is an easy matter, as this goes straight back to its own melting furnace. For engineering scrap the segregation is relatively easy if it is properly organized in each works, but the scientific sorting of old scrap presents much greater difficulties and requires careful organization to avoid waste. The higher prices paid for special alloys is an incentive to make the sorting as effective as possible. However, this is not so easy with small admixtures of alloy metals, and increasing difficulties are arising from the presence of these in undesirable quantities in the recovered metal.

One of the main difficulties of getting a true statistical picture of scrap recovery is the extent to which certain scrap is re-used directly without coming into the market. This applies to all process scrap and to a certain amount of engineering scrap which is recovered directly; for example, brass turnings go back direct to the brass foundry. In large organizations there is also a considerable re-use of old scrap which would not appear in any statistics. For example, railway chairs go back to the foundry, which may use as much as 95 per cent of old scrap. Bearing metals are also recovered internally and re-melted with the necessary additions of virgin metals which alone appear in the statistics. Similarly, copper scrap must reach the brass foundry unaccounted for, as the amount of copper used in brass making is less than the equivalent amount of zinc which is known to be used for this purpose.

The picture is complicated further by the re-use of suitable old scrap for the direct manufacture of other articles. For example, the re-rolling of old rails to produce a variety of articles is carried out on a considerable but unrecorded scale, and locomotive axles can be forged down and heat treated for crank pins of smaller diameter, or used for many other purposes. Small bars of mild steel can be used for drop forgings. The re-fabrication of old scrap has been greatly helped in recent years by welding, and especially during the War has made considerable progress. Much of this re-use of scrap which makes a considerable contribution to the conservation of mineral resources does not appear in any statistical review.

---

* Paper read on July 25 at the Conference on Mineral Resources and the Atlantic Charter, arranged by the Division for the Social and International Relations of Science of the British Association.

Relationship between Total Production and Scrap Recovery

The volume of consumption at any moment depends on new demands and on replacements due to obsolescence, corrosion and wear and tear. It is therefore clear that unless there should be heavy accumulations of scrap or new demands had vanished in a severe depression, the amount of scrap arising from replacements must always be less than the total amounts of metal required for current production. The relation between the two will vary with the metal metal and the circumstances.

With the modern tendency to rapid development and quicker obsolescence, the life-cycle of metals will in general be shortened. On the other hand, welding has made possible the repair of steel, for example at rail ends and in locomotive fire boxes, which will increase the service life of metals. The development of improved materials with increased hardness, greater resistance to wear and fatigue, and to corrosion (including painting and surface treatment) also tends to lengthen the life-cycle and eliminate losses of metal. The use of lighter designs, the increasing use of sheet metal and of a multiplicity of small 'gadgets' may, however, tend to make scrap recovery less complete.

LOSS

Life-cycle of iron

An interesting point arises in connexion with the increased use of reinforced concrete in place of steel construction. This effects a considerable saving of steel amounting to 50–60 per cent; but on the other hand it is not economical to recover much of the steel in reinforced concrete, whereas the bulk of a steel frame can be salvaged.

Relative Atmospheric Corrodibility of Metals

Metal	Friend (*J. Inst. Metals*, 42; 1929). 7 years in Birmingham City air. Loss of weight (%)	Hudson "Corrosion of Iron and Steel" (1940). Sheffield industrial atmosphere. Rate of corrosion (mils/year)
Mild steel	10·3	5·0
Wrought iron	6·7	3·8
Cast iron	3·5 (approx.)	Good resistance
Zinc	0·54	0·70
Nickel	0·47	0·41
70/30 Brass (2 Pb)	0·39	0·57
Copper	0·18	0·28
Aluminium	0·11	—
Tin	0·10	—
Lead (soft)	0·09	0·26
Stainless steel (12 Cr)	0·10	—
18 Cr 8 Ni	—	0·003

For iron and steel, corrosion is the biggest factor, which Speller estimates may lead to an annual replacement of two per cent of the total tonnage in use. For other metals the effect is much less, as is shown in the accompanying table giving the results of exposure of metals in the industrial atmospheres of Birmingham and Sheffield. The two sets of results are expressed differently, but the metals appear in the same order in each.

When all these variable factors are taken into account and the uncertain statistics as to the use of scrap, it is not surprising that it is impossible to draw up an exact balance sheet covering losses and recovery of any metal, as will be seen in the sections dealing with the separate metals.

Iron and Steel

At present iron and steel represent about 93 per cent of the total world tonnage of metal production, It has been estimated that of the total output, 15–20 per cent is lost from rusting, and that in all 35 per cent is lost irrecoverably due to rust, dispersal and the use of iron and steel in articles from which recovery is uneconomic. 65 per cent is left to find its way back into use, of which 25 per cent is process scrap which does not leave the steel works, and the remaining 40 per cent returns at a rate dependent on obsolescence, wear and the state of industrial activity. With improved protection against rusting, losses will be reduced, but quicker obsolescence will shorten the life-cycle.

The following figures for recent steel production in Great Britain confirm this estimate, remembering that some scrap goes to blast furnaces and that an addition must be made to the percentage of scrap in the table to allow for this:

Year	Total production	Pig used	Scrap used	Scrap (per cent)
1935	9·6	4·6	5·8	56
1936	11·8	5·6	6·9	55
1937	12·9	6·2	7·5	56

The recovery of ferrous scrap in the United States has reached a higher figure in recent years, averaging 75 per cent of the steel production, possibly due to quicker obsolescence.

The main difficulty which has arisen in the recovery of ferrous scrap is due to the increase in the number of alloys, which makes it increasingly difficult to segregate scrap of similar character. The result is that the amount of the residual elements tends to increase in ordinary steel, producing undesirable results. For example, the presence of nickel and chromium may produce a steel very different in characteristics from the steel required. Rejection has occurred from this cause, emphasizing the importance of improved methods for segregating most carefully scrap from alloy steels of various compositions, in order to utilize them most economically and to avoid the presence of elements which may upset the normal properties of the steel. The introduction of controlled grain size straight carbon steels often avoids the need for using alloy steels, and they have the additional advantage of simplifying the recovery of scrap, since they contain no other elements.

In the case of alloys with a high percentage of other elements, for example stainless steel or tool steels, the large differential in scrap price is an incentive to see that they are kept separate.

Manganese, Nickel and Chromium

There is only a small recovery of manganese in the form of high manganese alloys, as the bulk of it is used in steel manufacture as a deoxidizer and desulphurizer and is lost in the slag.

Only a small percentage of nickel is recovered, as much of it is lost in low-nickel steel alloys which go into ordinary scrap or in nickel plating. Undoubtedly more could be saved by the segregation of nickel alloys. Recovery is presumably better for the high-nickel alloys. In the United States scrap recovery has progressed steadily and in 1938 was about 2,000 tons.

Little is known about the recovery of chromium, except that its high price encourages recovery by producers and fabricators of the alloys and by large consumers. The expanding demands for chromium steels will make the segregation of chromium alloy scrap of increasing importance.

Copper

The United States statistics for copper recovery are more complete than for any other metal and so it is possible to give a clear picture of the position. Owing to its relative freedom from corrosion, wastage should be relatively small and its value is favourable for salvage.

Copper is recovered and passes into use again both as metal and as brass and other alloys, and it is important to distinguish between the two. United States statistics for 1929–38 show that, of the domestic consumption of copper metal, approximately 6½ million tons in those years, 2⅓ million tons, or 39 per cent, came from scrap recovery, of which roughly one third came from new scrap (process and engineering) and two thirds from old scrap. Scrap recovery in addition yielded nearly 2 million tons of copper in the form of brass or alloys. The total contribution of recovery, therefore, to the domestic use of copper in all forms was approximately 50 per cent for this period.

The trend of scrap recovery over a period of years shows a close relation to the index of industrial production. Increasing prosperity means new consumption and the quicker replacement of obsolescent articles. Increased production means increased new scrap, and the flow of old scrap depends on the rate of replacement. Apart from stocks this flow is, in fact, a direct function of current consumption. Hence it is not surprising that the volume of scrap recovery of copper should be related more closely to the index of production than to current scrap prices. The length of the life-cycle of copper will vary with the level of industrial activity.

Tin

About half the total tin production is used as pure metal for making tinplate and as foil for various purposes. The rest is used in various alloys, solder, bearing metal and bronzes. Tin is recovered from the clean tin scrap and from the dross arising in the course of manufacture of tinplate, but the recovery of tin from used cans is not in general economical owing to the difficulty of collecting and cleaning them. There is also a considerable recovery from tin alloys. United States statistics for 1929–3 show a recovery of metallic tin from scrap amounting to eight per cent of the total consumption as pure tin and alloy, and a recovery in the alloy form amounting to 26 per cent, so that on an average one third of the consumption was provided from the recovery of scrap. About 6 per cent of the tin is used in various chemical compounds and this is irrecoverable.

Lead

The major uses for lead are storage batteries, cable covering, sheet and pipe, and a small proportion is used in alloys. The processes of manufacture are relatively simple and they result in little process or engineering scrap. Owing to the relatively large percentage of lead used in pigments, in ammunition and as tetra-ethyl lead in motor spirit, and the loss of bearing metals by wear, there is inevitably a considerable irrecoverable loss. On the other hand, the recovery from storage batteries probably amounts to 80 per cent after an average cycle of two or three years in motor-vehicles, while the cable covering is also largely recovered after a longer period of years.

United States statistics for 1929–39 show that the recovery of lead as metal produced 1,349,000 tons, one third of the total production of refined lead during that period, and that, in addition, 1,017,000 tons were recovered in the form of alloys, thus saving an equal quantity of virgin metal.

Zinc

A large proportion (probably 40 per cent) of zinc production is used for galvanizing iron to protect it against corrosion, and none of this is recovered, the zinc being sacrificed for the protection of the so-called iron, but which to-day is mild steel. However, there is a wastage of some 20 per cent of zinc in the galvanizing pot, much of which is recovered as dross, which is re-distilled for spelter or zinc dust. The next largest use of zinc is for brass-making, a considerable proportion of which is recovered and re-used. Apart from this, there is only a small recovery of zinc from the articles in which it appears in the rolled form. The United States statistics show that the recovery of zinc as metal has averaged 11 per cent of metal production, and in addition slightly less has been recovered in the form of alloys. A considerable loss occurs each year from the use of zinc in pigments.

Aluminium

There is a considerable scrap recovery of aluminium and aluminium alloys. Process scrap is usually remelted in the works when it is produced. Engineering scrap (turnings, millings, filings, etc.), which may amount to 50–200 per cent of the weight of the finished article, requires special methods of melting to ensure both a good yield and quality and is usually returned to specialist firms, the secondary metal melters. The segregation and cleaning of the various types of scrap are of great importance.

Old scrap presents a more difficult problem, as it has to be separated into the different alloys, a skilled job requiring experience and the use of scientific methods.

United States statistics for 1929–38 show that out of a total production of one million tons of metal, one fifth came from scrap recovery. In addition, about 225,000 tons of aluminium were recovered in the form of various alloys, making the total contribution of scrap to consumption in this period about 35 per cent.

Export of Scrap

Nothing has been said yet about the export of scrap, but to secure maximum recovery there should be a flow back to metal-producing from non-producing countries. The statistics for iron and steel scrap, which are fairly complete, do show this in a few cases, such as Holland and Switzerland, but the bulk of the transfer of scrap, which averaged 5 million tons a year for 1933–38, actually took place between steel-making countries, owing largely to preparations for war. Under happier auspices the International Scrap Convention, established in 1937, might have done much to avoid this uneconomical transfer.

Conclusion

The absence of world statistics on the recovery of scrap makes it impossible to give a comprehensive picture of its full significance. However, it is clear from the data given above that scrap recovery will be of increasing importance as regards the conservation of our metal resources, and that as a major source of raw materials it must be brought into any general scheme affecting them under the Atlantic Charter.

Taking conservation first, the following measures would help towards a maximum scrap recovery and help to diminish wastage of metals : (1) The salvage of all new and as much old scrap as possible. (2) Improved methods for segregating engineering scrap of different kinds so as to avoid mixing different metals and alloys. (3) Improved methods for sorting and cleaning old scrap and identifying doubtful material by quick tests. (4) Improved methods for cleaning scrap and putting it into a suitable form for remelting. (5) Arrangements to avoid losses by corrosion when scrap, often finely divided, is kept for long periods. (6) Avoidance of the unnecessary use of alloys, which complicates scrap recovery, and the reduction of the number of alloy specifications to the minimum necessary. (7) Improved methods for protecting metals against corrosion. (8) The re-use of old scrap by fabrication and welding.

Turning now to the inclusion of scrap metals in any general scheme for metal supplies under the Atlantic Charter, the first essential is the compilation of international statistics on an agreed basis. Even if these cannot be complete owing to the difficulty of including old scrap which is re-used by works internally, and so-called runaround scrap such as bearing metal, which circulates internally and therefore does not come into account, it should be possible to collect data for all process scrap, engineering scrap, or old scrap which reaches the market, so as to see to what extent consumption in each country can be met from virgin metal or from scrap.

The need for such statistics was emphasized in the following passage from the report of the National Resources Board of the United States appointed by President Roosevelt in 1934 : "The subject of scrap is the great blind spot of the world's metal economy. Despite the importance of secondary metals no statistics of an international character can be had. The United States is the only Government compiling figures of secondary metal production. The present annual statistics of the Bureau of Mines should be established on a quarterly or monthly basis and expanded to include stocks and consumption as well as output. This is one of the most constructive steps that could be taken for stabilization of the metal industries. Until the importance of scrap is recognized, effective adjustment of supply and demand in the metal industries will remain difficult or impossible." This was written in 1935 with special reference to the United States ; to-day, in the light of the Atlantic Charter, it has a much wider significance.

FAMILY SIZE AND SURVIVAL IN GREAT BRITAIN

By Dr. PERCY STOCKS

THE Registrar-General's first report on fertility, based on the data obtained under the Population (Statistics) Act of 1938, shows that in 1938 the reproduction rate in England and Wales, adjusted for the anticipated rates of survival of women and girls, must have been between 16 and 20 per cent below the replacement level, and that if a serious decline in the native-born population of Great Britain is to be averted, the rate must be raised to that extent within the next few years. Complete elimination of stillbirths and child deaths up to age fifteen would bring us within 6–7 per cent of the goal, but that is outside the bounds of possibility. The increase might be effected by less avoidance of marriage and by marriage at an earlier age, but if no such social changes as these occur, it can only come by increase in the average number of children per family.

The average citizen has little knowledge of a biological kind as to the best age for marriage and the most favourable spacing of children for the rearing of a healthy family, and even scientific men have to confess to a lamentable lack of concise information on these vital matters. It would be natural to expect, therefore, that any addition to such knowledge would be eagerly studied. Little comment has been made upon the facts revealed by the fertility report : such as the findings that 42 per cent of marital children born in 1938 were first children, whereas only 19 per cent were born to mothers who had already had more than two, and that the risk of stillbirth was 30 per 1,000 for first-born and less than 20 for subsequent children to mothers less than twenty-five years old, whereas for first-born children it was 45 at ages 25–34 and 87 at 35 or over. Another important fact discoverable from the Registrar-General's 1938 report is that whereas the risk of maternal death when confinement occurs between the ages of 20 and 25 is only 1·5 per 1,000 maternities, it rises to 3 at ages 30–34, to 4 at 35–39 and to 6 at 40–44. The risk of a stillbirth increases from 28 per 1,000 births when the mother's age is 20–24 to 32, 39, 54 and 70 at succeeding age groups of five years. For young mothers under 20, both risks are slightly greater than at 20–24. Here is an important fact which should be stressed, namely, that the dangers to both mother and child are least when confinement occurs between the ages of twenty and twenty-five.

The Population Act statistics can tell us little about the survival of live-born children according to family size and maternal age, and we have little reliable data on this point since the census of 1911; but this gap has now been partly bridged by a study of the records of health visitors of the maternity and child welfare area of the Administrative County of Durham for the years 1930–37 by Mrs. C. M. Burns*.

This book needs careful study, for not all the conclusions, even when in the heavy type liberally used, can be accepted as proved by the data tabulated. From the point of view of survival up to five years, the report shows that first, second and third children are best born while the mother is between twenty and thirty-five, whereas fourth and fifth children have a better chance if born to mothers of 35–39 than if born to younger mothers; but the attempt which is made to prove that the latter finding is not the result of some form of social selection is not entirely convincing.

Nor can the evidence for the statement that "high death rates are more dependent on the size of family than on the housing conditions, as measured by rooms per person or rooms per family" be accepted as conclusive. First children of miners born to mothers aged 20–29 and housed at average densities of 1·1 and 1·8 persons per room respectively suffered losses before the fifth birthday of 147 and 143 in each 1,000 live or stillborn, whereas miners' sixth to ninth children born at any age of the mother and housed at average densities of 2·2 and more than 3 per room respectively suffered losses of 201 and 238 per 1,000. But no effect of overcrowding on health would be expected until the density exceeds about two persons per room, so the equality of the first two rates proves nothing; and the rising rates in the last two groups may as well have been due to overcrowding as to rapid breeding, these being so inseparably connected as to defy any statistician to disentangle them. It has long ago been demonstrated from the national statistics that mortality of children aged 1–5 years is more sensitive to environmental conditions than is infant mortality, and there can be little doubt that the presence of five other children in an overcrowded home is more likely to enhance the risks to a young child from most infective diseases than the presence of an equal number of adults.

The evidence that longer spacing between births results *per se* in better survival seems to have been based mainly upon a comparison of 119 sixth children born to mothers aged 25–29, of whom 28 or 23·5 per cent failed to reach their fifth birthday, with 353 sixth children of mothers aged 30–34 whose non-survival rate was 17·6 per cent, and upon similar differences in survival of the five previous children. This is slender evidence on which to base a far-reaching conclusion. That rapid breeding and overcrowding are each deleterious to the survival of young children may be accepted from the evidence, but it remains unproved which of the two is the more important.

The method of basing 'death-rates' of children upon the original number of live and stillbirths of which they were the survivors may lead to strange fallacies, such as the conclusion that twin children who have survived the first year thereafter "display quite normal death-rates". The data show that 414 per 1,000 twins failed to survive a year compared with 112 per 1,000 single born, and that the 'rates' at 1–4 years were 27 and 31 respectively; but if based upon the numbers at risk to die, the true rates at 1–5 years were 46 and 35 per 1,000 respectively, which shows the conclusion to be fallacious.

A conclusion which must occasion surprise is that in small families of one, two or three children "the fall in infant death-rates during this century has been very slight". It is deduced from the 1911 fertility report, by what method is not stated, that infant mortality in 1905–10 in families with one child was then about 55 per 1,000. Actually for marriages of 2½ years average duration, 62 per 1,000 first children born alive were dead at the census, and since the average interval between marriage and the first child, when that child was born in the first five years, was 1·63 years in 1938 according to the recent official report, and is unlikely to have been less than 1·5 years in 1905–10, the original figure 62 seems a more probable estimate for mortality of first children within a year than 55. By applying the Durham infant mortality-rates for children of successive birth ranks to the distribution of 1938 births in England and Wales according to birth rank, it can be estimated that the rate for first-born children was then about 92 per cent of that for all children (53), which gives 49 as the 1938 rate among first-born. Although a fal from 62 to 49 can scarcely be described as "very slight", it is small compared with the 50 per cent drop in the total infant mortality-rate, and Mrs. Burn has at least succeeded in showing that a large part of the improvement in infant and child survival in Great Britain on which we are apt to pride ourselves must have been due to the reduction in average size of family.

Mrs. Burns has produced with great industry a work so challenging that it will be widely quoted, and for that reason it has been deemed important to pu those who study and use it upon their guard against its faults. If it is unnecessarily gloomy we shall not quarrel with it on that account, for it contains much information which is unique and timely. The fertility position has got to be faced, and we cannot hope to apply the right remedies without a diagnosis of the causes. It is cheering to read in this report, based as it is upon conditions in a depressed area, that "If marriages take place early enough it would be quite easy to produce a fairly large proportion of well-spaced families of four, five or even six children under the best 'biological' conditions".

PUBLIC HEALTH IN GREAT BRITAIN

By Sir GEORGE NEWMAN, G.B.E., K.C.B.

FOLLOWING precedent in time of war, the Ministry of Health under the vigorous leadership of its Minister, Mr. Ernest Brown, has just issued a "Summary Report" on the public health of Great Britain from April, 1941, to the end of March, 1942* ; this is instead of the usual annual statement by the Chief Medical Officer. It is recognized that war has the effect of re-distributing the population, affecting the incidence and mortality of disease, and producing a variety of emergency services of a temporary nature (evacuation, raid shelters, and the care of the homeless). Nevertheless, it is highly satisfactory that the health of the people of Great Britain has been more than maintained ; and this indeed has contributed substantially to the war-effort itself. This high standard is attributed largely to the improvement made in matters of health, housing, nutrition, and the wider general public services accomplished in the last two decennia. "It owes much to the improvements in housing, health and other social services that were made between 1919 and 1939, and also to all that was done during the same 20 years to educate the public in health matters." The schools of all grades, the public newspapers, the B.B.C., and the most admirable work of the Ministers of Food and Agriculture in regard to rationing, agricultural development, and domestic application, each of which is a national science and art, have co-operated ; and at the back of it all, and inspiring it all, there has been an expanding public appreciation of what is at stake in the cause of freedom. In fact, this is one of the outstanding agencies serving as a lively stimulus of public opinion ; developing a sense of devotion and service, and of mutual interdependence, necessary to a State that is set on winning a war ; this 'something' is a kind of generative 'human credit', something to bank on, which when it grows in volume and extent inevitably leads to triumph of a constructive kind of statecraft.

Consider this astonishing fact. In the midst of the international struggle which has involved us all, and all our affairs down to the smallest detail, the English people have re-discovered their sense of solidarity and essential unity in purpose, with its consequent demand on their service, not only in the fighting line but also in what has come to be thought of as the 'home front', in maintaining the fundamentals of civilized life in Christendom, and its ordinary decencies. It is most impressive and enheartening. Instead of capitulating to the monstrous demands and outrageous policy of a group of gangsters, they have suddenly found themselves and their own soul. Life is after all not hedonistic ; nor is it the common thing which they had assumed, but a great and even glorious adventure. Are we really to suppose that Russia, and America (north and south), and China (which has come down through the ages), as well as Great Britain and her Dominions, are under some delusion that a monomania of Hitlerism and his New Order is the last word in human civilization ? If so, it is a grave misapprehension.

The redistribution of population in Great Britain due to the War called for sacrifice, both from the evacuated and those who received them. The local government service accepted the strain of the duty thus imposed upon it, and its reputation for efficiency and devotion was if anything enhanced ; by 1940 and 1941, accommodation had been organized for 3 millions in public and communal shelters and 4½ millions in Anderson shelters. The absence of 'alerts' towards the end of 1941 relieved the Ministry of a most exhausting effort, central and local, and allowed it to attend to the routine duties of health.

The general health all through 1939–42 has remained excellent. The total death-rate was 12·1 per 1,000 in 1939, and 12·9 in 1941. The *infant mortality*, which by 1939 had been reduced from the 'homicidal' figures of earlier years (such as 150 per 1,000 from 1870 to 1900—involving the loss of 140,000 infant lives yearly) had come down to 90 in 1916–20 and to 60 by 1930 (that is, a loss of 38,000 children) and was in 1939 so low as 50, moving up in 1941 to 59 (representing 34,000 deaths of children less than one year of age).

The *maternal mortality*, as is well known, changed for the better in 1934. Before that date, Great Britain had been acquiescent in losing the lives of 3,000 every year, but in 1932 the figure declined to 2,500 and in 1940 to 1,640. This meant a fall in the maternal mortality from upwards of 4 or 5 per 1,000 to 2·6, the lowest on record. This welcome and extraordinary reduction is rightly attributed to improved midwifery, and especially to an improvement in the treatment of puerperal sepsis, by the use of sulphonamide. How was it done ? The answer is clear. The fall in the infant and maternal mortality was due to *better motherhood* and better midwifery practice. In other words, the physical functioning of motherhood is not hereditary, but must be learned by each mother ; and three or four years ago it was discovered, medically, that by the wise use of sulphonamides puerperal fever might be reduced. The State and voluntary agencies did their part for mothers and children by establishing infant welfare and ante-natal centres where the art of midwifery and the care of infancy might be taught ; 3,600 of these centres were established by local authorities or voluntary agencies by 1941, and they were attended by 70 per cent of all the babies born alive in that year. There were also 1,800 ante-natal clinics, and many hundreds of health visitors visited in the homes. The National Milk Scheme provided free milk for mother and baby, and eggs, free oranges and lemons, or orange juice, blackcurrant juice or purée, and cod liver oil. The Government also provided many new nurseries and contracted for others, and by March, 1942, there was new accommodation for 11,400 children ; and in addition there were 2,000 hostels provided for mothers or children, or both. The exaggerated talk about 'malnutrition', before the present War began, has died down, and what has been said here shows how keenly interested the Government has been in protecting the mother and child from any degree of under-nutrition. Investigations show nothing disquieting ; indeed the reports from many [illegible]stricts show evidence of improvement.

Owing to the rise in the incidence and mo[illegible] of *diphtheria* the Ministry has urged the public [illegible]ve children immunized against this infection. In 1941 a campaign was initiated by Sir Wilson Jameson, broadcasting the favourable experience of New York in this matter, and up to June, 1942, upwards of three million children in Britain had been inoculated.

---

* Summary Report by the Ministry of Health for the Period from 1st April 1941 to 31st March 1942. (Cmd. 6394.) Pp. 35. (London: H.M. Stationery Office, 1942.) 6*d.* net.

It is curious to remember that England, the home of vaccination against smallpox, is slow to practise immunization. It waited fifty years, and lost many lives, before it used its own inventions; similarly with diphtheria and typhoid. *Tuberculosis* also has been a cause of anxiety owing to an increase of 23 per cent among industrial young women. The avoidance of droplet infection, the use of pasteurized milk, and miniature radiography in diagnosis are recommended.

Venereal disease is a still more complex problem, which tends to increase in importance in war-time. The Royal Commission of 1916 elucidated it and directed attention to the importance of early diagnosis, free treatment, the use of Salvarsan or its derivatives, and the prohibition of quack advertisements, false remedies, and unqualified practice. It also advised widespread public education, and numerous clinics, of which some two hundred were established. In March of the present year, the Central Council for Health Education was authorized to assist in the necessary educational work (see also NATURE, Nov. 7, p. 529). Notification of venereal disease was not recommended in 1916, as it tends to drive the disease underground; but its present tendency to rise in incidence is full of warning as to the need for alertness and vigilance. The reaction of the Ministry of Health to the problem is seen in a Defence Regulation (33, B.) issued on November 11 (since the "Summary Report" was published) announcing that, particularly because of the presence of numbers of service men and women from countries where treatment of venereal disease is compulsory, treatment is now made compulsory in Great Britain.

Happily this is not all. For the Minister of Health has an eye to the future reconstruction of the public health services, and his advice on this subject is much to the point. The prior aim to meet the admitted needs of mothers and children, which has proved itself most effective, is not enough; and in 1941 the Minister laid down the principles of his particular "New Order". There must be no return after the War to the confused and unrelated hospital services pursuing independent, wasteful, and competitive courses; the hospital business must be *planned* as a whole into a comprehensive and adequately integrated national service by which everyone in need will actually receive appropriate and prompt treatment. This is to be undertaken by the larger local authorities (in close co-operation with the smaller) and in recognized co-operation also with the voluntary hospitals, in areas substantially larger than those of existing local authorities. This meets the new demand for regionalization. Further, the Exchequer should give financial help, especially to hospitals undertaking the teaching of medical students or the highly specialized services of medicine, surgery and practical midwifery. To this end the Minister of Health has instituted a system of survey of the present administrative situation, beginning in the London district, and also an inquiry into organization of the medical schools, and their arrangements for clinical teaching and research. Such inquiry will not include the curriculum of medical training, already provided by the General Medical Council under Act of Parliament. Nor has the Minister lost sight of two new spheres of applied medicine, industrial and rehabilitation. We must complete our medical treatment (vocationally or otherwise) by following up effectually our remedy, so that the industrial worker who has been disabled may be returned to his job fit to continue his work, or any new work to which he may be transferred. All this is very timely and hopeful; and it envisages a long-felt need for co-operation with medicine of the rehabilitators, the vocationalists, and the medical specialists.

NEWS and VIEWS

Dr. D. R. Pye, C.B., F.R.S.

DR. DAVID RANDALL PYE, formerly fellow of Trinity College, Cambridge, and of New College, Oxford, has been appointed to succeed Sir Allen Mawer as provost of University College, London. Dr. Pye, who has been for many years connected with the scientific side of aeronautics, succeeded Mr. H. E. Wimperis as director of scientific research to the Air Ministry, which appointment was transferred by a war-time change to the Ministry of Aircraft Production. In this position he has had control of a large scientific and experimental staff, principally at the Ministry's London headquarters, the Royal Aircraft Establishment at South Farnborough, and the Aircraft Testing Station at Boscombe Down. He has also worked in collaboration with the Aeronautical Research Committee, and the National Phys[illegible] Laboratory, Teddington, and has been re[illegible]ble for maintaining the high standard of sci[illegible] aeronautical research in Great Britain.

[illegible]ye's own original scientific work was on the internal combustion engine, and he is the author of a standard work in addition to many papers on this subject. His administrative work at the Air Ministry has covered all the other branches of work associated with the development of aeronautics, and the production and use of aircraft in the widest sense. He was elected a fellow of the Royal Society in 1937, and is a past vice-president and member of the Council of the Royal Aeronautical Society. He is also one of the general editors of the Oxford Engineering Science Series of works.

Akbar, the Great Mughal

ON November 23, 1542, Akbar, the future Mughal Emperor, was born at Amarkot. His father, Humayun, had already lost the kingdom won by Babar, and Akbar's childhood was spent in exile. Humayun reconquered India in 1555, only to die, and the boy-king had to endure five years of regency before he came into his own. He stands out among Asiatic rulers as a determined leader and enlightened organizer. But the man was greater than the king. His interest in religion and philosophy, art and science is famous, but the distinguishing marks of his greatness were the questing intelligence and fearless judgment he consistently brought to bear upon the difficulties with which he was surrounded. He set himself to unite Hindu and Muslim India. He married into the ancient Rajput royal families, and

Jahangir, his successor, was born of a Rajput princess. It is worth remembering that his reign coincides almost exactly with that of Elizabeth of England. At a time when Europe still found the methods of the rack and stake acceptable, he instituted and enforced religious toleration. He grappled with the horrors of suttee two hundred years before Bentinck abolished it. He was the patron of learning and the arts. His justice knew no distinction of caste or creed or colour. Such was the man, who, while he lived, united India in mutual service. The fourth centenary of Akbar's birth will be celebrated by a meeting arranged by the British Council, the Royal Asiatic Society, the East India Association and the India Society to be held in the rooms of the Royal Society on November 23.

Discovery of a Nova

A TELEGRAM from Lund announces the discovery of a nova, magnitude 2, by Finsler and Nakahara. It is about 5° north of ζ Puppis. The telegram is dated November 13, but the time of discovery is not stated. Before receiving the telegram a telephone message which was sent by Mr. G. Ellis, Llandudno Junction, was received at the Royal Observatory, Greenwich, and this announced that Mr. Ellis, observing from a height of 400 ft. above sea-level, had discovered the nova on Nov. 13d. 4h. 25m. U.T., its approximate position being, R.A., 8h. 10 m., Dec. – 34°. Owing to its high southern declination it will not be an easy object to see in Great Britain. It crosses the meridian about 4h. 15m. U.T. on November 21, and in the latitude of Greenwich its greatest altitude does not exceed 4·5°. Mr. Will Hay has reported that he has observed the nova with the naked eye.

Documentation and Microfilm

THE *Proceedings of the British Society for International Bibliography*, Parts 1 and 2, contain the papers and discussions at the twenty-second and twenty-third ordinary meetings on March 5 and April 23 last, respectively. In Part 1, Miss M. Shaw's paper "Documentation in an Industrial Laboratory" describes the library and information service in the laboratories of Messrs. J. Lyons and Co., Ltd. The function of this library is to keep the chemical staff supplied with the most recent scientific and technical literature, to see that this is adequately catalogued and indexed, and to supply information, as well as prepare bibliographies and translations. Any books borrowed must be in the laboratories during the day so that they are available for reference if required. With regard to abstracting, the actual reading of the periodicals and selection of matter to be indexed is carried out by the chemists themselves, the periodicals concerned being issued to the sections of the laboratory in turn, for periods of 2–3 days, and 7 days for the final section, which is responsible for noting anything missed by other sections. Indexing is carried out daily in the library before re-issuing a periodical. For copying scientific papers, the Lumiere – Van der Grinten diazo process is used and has given very satisfactory results since July 1938.

Part 2 of the *Proceedings* contains a paper by B. K. Johnson describing four pieces of apparatus for use with microfilming processes. These consist of a hand viewer for the recognition of titles and general identification of the film; a viewer for table use, a microfilm projector for use by the typist when typewritten copies of a document recorded on microfilm are required, and a camera for the photography of documents, etc. In a written communication in the discussion, Mr. E. H. Lindgren stressed the importance of proper safeguards in the storage of the film and referred to an intensive technical examination of the films in his possession which is being carried out with the view of obtaining fuller information on the storage question. Mr. K. S. Smith's paper in the same part describes the airgraph service, Mr. H. J. Dowden the Gesteprint process for duplicating foreign periodicals, etc., in which the stencils are prepared by a photographic process, and a paper by H. Rottenburg on "The Typewriter as the Foundation of the Printed Book" outlines the possibilities of replacing printer's type by a typewriter and discusses the advantages.

Polarography

POLAROGRAPHIC methods continue to attract attention in Great Britain. Much knowledge has already been obtained and a concise summary of this, written in a simple objective manner, is to be found in a pamphlet, "Cambridge Polarograph", recently published by the Cambridge Instrument Company. For its size this pamphlet covers a great deal of ground and, if the theoretical background of polarography is largely omitted, this is compensated for by the presence of a considerable bibliography which contains references to most of the important papers on the subject. The difficulties of the polarographic method are not unduly emphasized; nevertheless, most of the major pitfalls are mentioned and it is frequently made clear that modifications of technique must be very critically tested. Use of the polarograph for the performance of amperometric titrations has not been overlooked.

A relatively small part of the pamphlet is devoted to a description of the Cambridge polarograph, and it is a pity that a wiring diagram of the instrument is omitted. Clearly, however, satisfactory electrical equipment is provided in a compact form to meet the needs of a present-day user of the polarograph. The text of the pamphlet is well illustrated with reproductions of actual polarograms, which give a very fair idea of the possibilities of the instrument and will no doubt stimulate the efforts of new users of the Cambridge polarograph. A table and chart of the half-wave potentials of inorganic substances, and the bibliography already mentioned, add to the value of the publication.

Spectroscopy in Astrophysics

DURING a conference on spectroscopy arranged by the University of Chicago on June 22–25, several papers described results of recent research with the aid of the spectroscope. A short account of these papers is given in *Sky and Telescope*, September, by Dorrit Hoffleit. Dr. Andrew McKellar, of the Dominion Astrophysical Observatory, has made a critical study of the intensities of bands in the spectra of Comet Hassel (1939*d*) and Comet Cunningham (1940*c*). These bands correspond to temperatures ranging roughly from 200° to 2,000° K., and further research is desirable to explain this anomaly. The use of the spectroscope in settling the composition of planetary atmospheres has been followed by numerous theories to account for the diversity in the atmospheres of the planets, assuming that they all started their evolutionary course as homogeneous fluid masses with temperatures of several thousand degrees. Dr. Rupert Wildt discusses this problem in an interesting paper, but, as might be expected with a subject of such complexity, there is a large amount of speculation in his theories. Dr. C. T. Elvey reports on spectrophotometric and photo-electric studies of the night sky, and discusses the permanent or 'non-polar' aurora, which is much less spectacular than the better known northern or southern lights. The spectra indicate that atoms or molecules of oxygen, sodium, nitrogen, nitric oxide, water, and sometimes ionized nitrogen are involved. Spectrophotometric studies, in which Dr. Alice Farnsworth collaborated, refer to radiations originating about 800 miles above the earth's surface. Photo-electric observations concern radiations from altitudes of about 200 miles. Infra-red observations of the intensity of the light of the night sky show that there is sometimes a steady decrease throughout the night, and also that such observations are associated with times when terrestrial magnetic activity is low. It is suggested that this regular variation may be explained on the theory that the radiation is caused by the release of energy when oxygen atoms combine to form oxygen molecules.

Recent Earthquakes

AN earthquake with epicentre in the Songea District (Livingstone Mountains) near Lake Nyasa, Tanganyika, was reported from Dar es Salaam on November 8. It is said to have been the most serious for many years and wrecked many buildings and a Roman Catholic mission. Damage is estimated to have been near £3,000. No casualties have been reported.

Dr. Perry Byerly of the University of California reported the registration of a very large earthquake by the seismographs at Berkeley at 8.2 a.m. Eastern War Time on November 10. The epicentre was estimated to have been 9,500 miles from Berkeley.

During October 1942 only two important earthquakes have been registered by the seismographs at Kew Observatory. These were on October 20 and 26, respectively. The former began recording at 23h. 35m. 55s. U.T. and attained a ground amplitude of 195 μ at 00h. 27m. 06s. on October 21. The epicentral distance from Kew may have been 11,200 km., but the analysis is tentative since the record was interrupted by large microseisms. The latter began recording with compressional *iP* on all three components at 21h. 21m. 19s. U.T. and attained a maximum ground amplitude at Kew of 89 μ at 21h. 56m. 57s. U.T., the recording being complete at 23h. 55m. U.T. The epicentre may have been 8,700 km. from Kew, almost in a south-westerly direction. On October 30 an earthquake shock of considerable strength was reported from Switzerland. No further details are so far available.

Reginald Farrer (1880–1920).

THE pre-war vogue of rock gardens owes much to the enthusiasm of Reginald Farrer (1880–1920). His home was in Ingleton, Yorkshire, where the natural scenery is itself a rock garden, and Farrer began to combine this beauty with horticultural concentration of colour at the early age of fourteen. Two short papers by E. H. M. Cox, one of Farrer's collaborators, and Humphrey Denham (*J. Roy. Hort. Soc.*, 67, Pt. 9; 1942) portray Farrer's life and his contributions to gardening. Having exhausted the possibilities of the European Alps, he made two expeditions to China; from that country he introduced the beautiful threepenny-bit rose (*R. Farreri*), *Buddleia alternifolia*, several species of Rhododendron, *Aster Farreri*, *Viburnum fragrans*, and many others. Aside from his botanical contributions, Farrer's life is an outstanding study in determination; he had very poor physique and was "a Yorkshireman with an inferiority complex", yet his contributions to horticulture rank among the greatest.

John Amos Comenius

ON October 24, 1941, the tercentary of the visit of John Amos Comenius to England was commemorated at Cambridge, and in NATURE of November 22 there appeared an account of Comenius, his life and work, by Dr. Gerald Druce. It was then intended that the papers read at the commemoration would be published in permanent form. This intention has been carried out by the appearance of a volume entitled "The Teacher of Nations", containing all the papers read, whether short or long (Cambridge University Press, 5*s*. net). The volume, which is edited by Dr. Joseph Needham, contains also a chronological table showing the events in the life of Comenius, by Dr. R. F. Young, and a select bibliography of the works of Comenius by Anne Heyberger.

British Rheologists' Club

AT the annual general meeting of the British Rheologists' Club, held on November 6, the following officers were elected: *President*, Dr. C. F. Goodeve; *Honorary Secretary*, Dr. G. W. Scott Blair; *Honorary Treasurer*, Dr. V. G. W. Harrison. After the formal business, Prof. E. H. Rideal gave an informal address on "Solutions of Macro-molecules". Later, simple demonstrations were given by some members of the Committee to illustrate the Club's "Table of Deformations" (NATURE, 149, 702; June 20, 1942).

Colonial Service Appointments

THE following appointments and promotions in the Colonial Service have recently been made: E. G. Cripps, agricultural officer, Nyasaland; G. R. Fenton, assistant conservator of forests, Sierra Leone; J. F. Hughes, assistant conservator of forests, Tanganyika Territory; C. C. B. Brown, veterinary officer, Tanganyika Territory; L. C. Stones, veterinary officer, Gold Coast; J. N. R. Brown (agricultural officer), senior agricultural officer, Tanganyika Territory.

Work of Scientific Men of the United Nations

THE Association of Scientific Workers is holding a conference on "Scientists of the United Nations and the War Effort" at Gas Industry House, 1 Grosvenor Place, S.W.1, on December 5 (2.30 p.m.) and 6 (11 a.m.), under the chairmanship of Sir Richard Gregory, president of the British Association. Prominent scientific workers from more than fifteen countries will give addresses on the destruction and distortion of science in the oppressed countries and will show by contrast the contribution of scientific men of the United Nations who are in Great Britain to the war effort. Applications for invitations should be sent to the secretary, Foreign Scientists Committee, Association of Scientific Workers, Hanover House, 73 High Holborn, W.C.1.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Effect of an Enzyme from Kidney on the Solubility of Calcium Phosphate

The precipitation of sparingly soluble salts in organs like kidney and liver can no doubt be due to a variety of reasons. In the following note an experiment is described which may possibly show the mechanism of one of them.

It has been demonstrated lately that the solubility of calcium salts is increased by amino-acids[1]. A man who keeps his calcium intake constant but eats more protein absorbs more calcium and consequently excretes more of it through his kidneys[2]. This makes it likely that a proportion of the calcium inside the body is in the form of composition compounds between amino-acids and calcium salts.

Most calcium precipitates are found in kidney and liver. These organs are also richest in enzymes destroying amino-acids[3], a process which should lower the solubility of calcium salts.

Whereas pig's kidney destroys both *l* and *d* amino-acids, the *l* amino-acid oxidase is insoluble in water and an aqueous extract will only attack the *d* compounds[3]. This fact is used to devise an experiment, which demonstrates the transformation by *d* amino-acid oxidase of soluble calcium phosphate into insoluble precipitate.

Two solutions of 20 per cent alanine are prepared, one of the *d* (−) and one of the *l* (+) compound. To 1 ml. of each are added 1 ml. *N*/10 hydrochloric acid saturated with $CaHPO_4$. The addition of 1·3 ml. *N*/10 sodium hydroxide makes the solution slightly alkaline, but no calcium phosphate is precipitated due to the presence of the alanine. Acetone powder from pig's kidney (prepared according to Krebs[3]) is extracted by ten times its weight of water. 1 ml. of the filtered extract is added to each sample; a capillary is immersed from which a constant stream of oxygen is supplied. Both solutions are left for one hour at 30° C. Only the one which contained the *d* (−) alanine shows a considerable cloudy precipitate. After centrifugation a positive nitroprusside reaction is given by the supernatant, a sign that alanine has been deaminated to pyruvic acid. The centrifugate is resuspended in dilute nitric acid and filtered. Addition of sodium acetate and sodium oxalate to the filtrate leads to precipitation of calcium oxalate.

Time factor. Whereas much of the deamination occurs in the first half-hour, most of the precipitation takes place in the second half-hour. The effect of amino-acids on the solubility of sparingly soluble salts takes time to show itself. If, for example, alanine is added to a suspension of freshly precipitated calcium phosphate, a considerable time will pass before all precipitate has disappeared. The same is true for the reverse process. This can be demonstrated in the following way. An experiment is carried out as described above, but both samples contain *d* (−) alanine. After half an hour one tube is boiled for one minute to inactivate the deaminase. It is quickly cooled down again and filtered. Almost as much calcium phosphate precipitate will appear in the filtrate within the next thirty minutes as in the untreated sample within one hour.

Another way to demonstrate the time lag between deamination and calcium phosphate precipitation is to filter a sample containing *d* (−) alanine after half an hour and to apply nitrogen instead of oxygen for the next thirty minutes. Although the amino-acid oxidase cannot act in nitrogen, precipitation of calcium phosphate will continue under these conditions. A control containing *l* (+) alanine will show no change in calcium phosphate solubility.

Some cloudiness can also be seen often in the samples with *l* (+) alanine. This is due to various reasons. One of them is denaturation of protein from kidney extract. The extract may also contain traces of iron which lead to a precipitation of ferric phosphate, the solubility of which is not influenced by alanine[1]. If after centrifugation the sediment is resuspended in acid and filtered, only traces of calcium can be discovered in the filtrate.

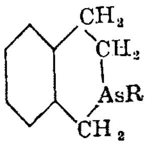
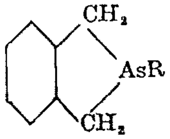
New Heterocyclic Systems

o-β-Bromethyl-benzyl bromide, $C_6H_4(CH_2Br)$-CH_2CH_2Br, has hitherto been available only by the very laborious synthesis of von Braun and Zobel[1]. We have now developed a new synthesis by which the dibromide can be prepared far more readily and in good yield. As von Braun and Zobel have shown, the dibromide condenses with primary amines to give N-substituted-1 : 2 : 3 : 4-tetrahydro-*iso*-quinolines. In view of the occurrence of the *iso*-quinoline nucleus in many natural products possessing marked physiological activity, we are now condensing the dibromide with a wide variety of amines, in order that the chemotherapeutic properties of the resulting *iso*-quinoline derivatives may be investigated.

(I)



(II)



We find also, however, that the dibromide condenses readily with alkyl (or aryl)-dichloro-arsines in the presence of metals to give stable 2-alkyl (or aryl)-1 : 2 : 3 : 4-tetrahydro-*iso*-arsinolines (I): these compounds possess a new heterocyclic system isomeric with that in the 1 : 2 : 3 : 4-tetrahydro-arsinolines discovered by Burrows and Turner[2].

We have prepared a number of such tetrahydro-*iso*-arsinoline derivatives, and are investigating the preparation of similar derivatives containing phosphorus, antimony, tin, etc., in place of the arsenic. The chemotherapeutic activity of the compounds so obtained will be tested.

o-Xylylene-dibromide also condenses with aryl-dichloro-arsines to give 2-aryl-dihydro-*iso*-arsindoles (II), but the yield of these compounds appears to be markedly less than that of the corresponding members of series (I).

Superconductivity and Liquid Helium II

WHEN discussing our observations on the transfer of liquid helium II along solid surfaces above the liquid level[1], we pointed out that this mechanism of surface flow might also be responsible for the 'transport phenomena' in the bulk liquid (high heat conduction, low viscosity and the fountain effect)[2]. Subsequent experiments by ourselves[3], Allen and Reekie[4] and by Kapitza[5] strongly support this assumption. It appears that the transfer film observed above the liquid level also extends below it, covering all solid surfaces in contact with liquid helium II, and it is evidently in this film that the anomalous transport phenomena take place.

It has been suggested by F. London[6] that the λ-phenomenon in helium may be caused by the existence of helium atoms of very low (or zero) thermal energy, and the mechano-caloric effect found by us[3] strengthens this view. This effect shows that by flow along a solid surface, such thermally 'unexcited' atoms can be separated to a certain extent from the bulk liquid.

In elaborating our hypothesis we have now come across a striking analogy between the phenomenology of liquid helium II and superconductivity, which seems to go much farther than a superficial similarity. While we have a good deal of information on the superconductive state, our knowledge concerning liquid helium II is very limited. A certain amount of generalization has thus been necessary in the formulation of our thesis, which therefore must be considered as of an approximate nature only. The main points of the analogy are as follows:

(1) As it is impossible to establish a difference of electrical potential at the ends of a superconductor, so it is impossible to establish a temperature difference along the transfer film of helium II.

(2) In both cases the frictionless transport of particles (electrons or atoms) breaks down as soon as a certain value of flow is exceeded. This limiting value is given by the current threshold in superconductors, J, and by the rate of transfer, R, in helium[1].

(3) In both cases this limiting value of flow is solely dependent on temperature and is independent of the length of the path the particles have to travel. It is directly proportional to the width of the connecting surface (this holds rigidly for plane surfaces, whereas for curved surfaces the limiting rate of flow will be reduced in both cases).

(4) In liquid helium as well as in superconductors, the frictionless transport seems to be confined to the geometrical surface of the substance. Kapitza[5] has demonstrated that an anomalously high heat conduction does not take place in the bulk of helium II; that is, there is no frictionless transport of atoms unless this can take place along a solid – liquid boundary surface. An analogy to this exists in a superconductor, since it seems theoretically impossible to remove an electric charge from inside a completely closed superconducting shell except by the process of normal conduction.

(5) It appears that in both cases the maximum current density of flow on the surface (J, R) indicates the number of particles which can at each temperature be transported frictionlessly (provided one assumes the particles to have velocities independent of temperature). The threshold curve and the curve giving the temperature dependency of R will therefore play an identical part in the treatment of both phenomena. Indeed the shape of these curves is similar; they both start with a finite slope at the temperature at which the first anomalous behaviour is evident, and they both become temperature independent near absolute zero.

(6) When developing the thermodynamics of a superconductor with the current density rather than the magnetic field as the variable of state, one arrives at a formalism which also fits well the observations in liquid helium II. While the rigorous derivation of this cannot be given here, it appears that R^2 assumes the same significance in determining the free energy of liquid helium II as the square of the threshold field has for superconductors[7].

(7) One would expect that in such a model the specific heat of the system of superconductive electrons as well as that of the 'unexcited' helium atoms would be zero. This seems actually to be the case. The facts that a super-current in a temperature gradient produces no Thomson heat[8] and that no heat transport exists in a helium film in a direction opposite to that of the flow[1] strongly suggest that no heat is transferred to the particles while they remain in the anomalous state. We ascribe the observed high specific heat of superconductive metals and liquid helium II to the energy taken up in lifting particles from the lowest state into thermal equilibrium with the rest of the substance.

The question naturally arises what physical significance has to be given to this striking analogy. It seems to us that the fundamental phenomenon is the passing at finite temperatures of a number of particles into the lowest quantum state, where no energy exchange can take place between them and the remainder of the substance. This new form of aggregation of matter evidently follows quite general rules, so that the fact that the particles are electrons in one case and atoms in the other is only of secondary importance. The phenomenon of frictionless transport confined, as it is in both cases, to the geometrical surface, might be explained by the fact that, as the particles are free from interaction with the bulk of the substance, they can only be accelerated by external forces. The range to which these external forces can penetrate the substance limits the layer in which the transport takes place. Thus, in a superconductor, electrons can only be moved within the depth of penetration of an external magnetic field[9], while the flow in a helium film is limited by the extent of the van der Waals' forces of the container. It appears from these considerations that the theoretical interpretations of the superconductive state and of the λ-phenomenon in liquid helium II should be similar in their fundamental aspect, and it is with regard to such a generalized theoretical treatment that we hope the analogy pointed out in this note will be of value.

Tensile Strength of Water and Liquid Structure Theory

THE following note arises out of work in this Department examining erosive action from the point of view of liquid structure theory.

In a recent paper[1], R. Fürth suggests a theory of liquid structure in which holes in a continuum are treated by statistical mechanics. The picture of the theory is almost the reverse of the kinetic theory of gases, since holes move in a continuum instead of particles in a void. The holes are, however, supposed to contain vapour at the vapour pressure corresponding to the temperature.

Fürth's treatment indicates the existence of the known metastable state in which the temperature exceeds the saturation value corresponding to the pressure, the vapour pressure exceeding the hydrostatic. For the limit of this metastable state he obtains the defining equation

$$p_0 - p^* = \frac{1 \cdot 3\sigma^{3/2}}{\sqrt{kT}}, \quad . \quad . \quad . \quad (F.27)$$

where p_0 is the vapour pressure corresponding to the temperature T, σ is the surface tension, p^* is the hydrostatic pressure and k is Boltzmann's constant.

Substituting the value of surface tension for water at the region of normal atmospheric temperature (10° C.), we obtain a pressure difference of 80,000 lb./sq. in. If p^* is considered to be atmospheric pressure, the excess of vapour pressure demands a high temperature before it can be realized, and in this case has little meaning since the pressure is above the critical. Actually, however, the right-hand side needs to be altered to allow for different T, including the variation of surface tension, and the two sides become equated for water at about 337° C., where p_0 is about 2,000 lb./sq. in.

In practice, this order of superheat has not been obtained, due to the presence of particles and dissolved gas. The highest value is of the order 180° C. recorded for water in the form of a globule suspended in oil at atmospheric pressure[2].

Equation $F.27$ may, however, be regarded from another point of view. It is generally taken that the hydrostatic pressure p^* is not less than zero and therefore that $p_0 - p^*$ cannot be greater than the vapour pressure at temperature T. But if p^* could be taken to be negative this conclusion would not follow. The above data indicate that $F.27$ would be satisfied were p^* of the order $-$ 80,000 lb./sq. in., since p_0 at 10° C. is then negligible.

This suggests that the liquid should theoretically carry a tensile stress up to the limit of p^*. From the above figures the theoretical limit suggested at usual temperatures would be of the order 80,000 lb./sq. in., that is, 35 tons/sq. in. Again, however, the disturbing influence of particles and dissolved gases in promoting evaporation will give an actual limit which may be much less. Using the ordinary equations for the equilibrium of a bubble of radius r, the tensile limit suggested will be between $2\sigma/r$ and $4\sigma/3r$. Even radii so small as 10^{-4} cm. would make this limit of order less than one atmosphere, and in ordinary circumstances evaporation nuclei much greater than this exist in water. Thus the tensile stress which can be maintained by water is negligible.

While nuclei may exist, evaporation will not occur unless a suitable temperature distribution is formed to allow the conduction of heat into the nucleus, and that at a limited rate governed by the distribution and by the surface area. Hence a tensile stress above the limit imposed by the nuclei may persist for a short time, and the value attained would seem to depend on the relative times for evaporation and for growth of the stress. The suggestion is, therefore, that the ultimate limit corresponding to p^* derived from Fürth's theory could be carried for an infinitesimal time and hence would be transmissible as a tensile wave of rectangular wave front. A very steep tensile wave front could be expected, therefore, to be transmissible through water. Some evidence on explosion waves in water suggests that a considerable tensile wave is transmitted. Poulter[3] cites experiments indicating "several hundred kilogrammes per square centimetre", but no precise data appear to have been published.

Iron Electrode Potential in a Magnetic Field

REFERENCE is made in text-books on magnetism to experiments by Paillot[1] and others in which potential differences such as 0·05 volt for 30,000 gauss were obtained between an iron electrode in the field and another which is not. It seems, however, that one should expect only the much smaller potential difference calculable by equating the magnetic energy change involved per c.c. (7·8 gm.) of iron (which is $(\mu - 1)H_2/8\pi$) with the corresponding electrochemical energy (which is $V \times 10^8 \times 7{\cdot}8 \times 10^{-1}/0{\cdot}000289$), whence we get $V = (\mu - 1)H_2 \times 1{\cdot}5 \times 10^{-13}$ volts, the values for various fields being :

$H =$	100	1,000	10,000	30,000 gauss
$\mu - 1 =$	180	21	*c.* 2·0	*c.* 0·5
$V \doteq$	0·26	3·1	*c.* 29	*c.* 67 microvolts

In testing the matter it was decided to use a permanent magnet, in spite of its lower field, so as to eliminate the possibility of stray potential differences from magnet coils. Preliminary trials with iron wire electrodes in a narrow cell, which could be slid between the pole-pieces of the magnet (*c.* 0·5 cm. apart) so as to put the two electrodes in the field alternately, gave potential differences of the magnitude found by Paillot, but rather irregularly and so slowly built up as to suggest that they were due to subsidiary causes such as reaction between ferrous salt and oxygen. This was proved to be the case by using a ferrous solution ($M/2$ $FeSO_4$) set by gelatine with a paraffin seal excluding air. Then a potential difference of about 2·7 μV. was regularly given as the field was switched from one electrode to the other. A first series of twelve rough observations gave the (single-direction) potential difference as 1·24 (± perhaps 0·2) μV., which corresponds to a field of 430 (± 70) gauss ; a second series of twenty-one better observations gave the value 1·35 (prob. error ± 0·07) μV., corresponding to a field of 480 (± 24) gauss : these values agree well with the result of determinations with a modified Quincke 'hydrostatic balance', which gave the field as 470 (± 40) gauss.

The small potential differences of this effect were observed by microscopic reading of the pointer of a moving coil galvanometer (with phosphor-bronze strip, not pivot, suspension), the resistance of the circuit reducing the correspondence of one division of the eyepiece to 5·5 μV.—specimen readings being:

+ 0·45 0·80 0·75 0·70 0·60 0·80
− 0·50 0·65 0·65 0·20 0·35 0·70,

these being 'drift' usually.

It is evident, then, this magnetic effect affords no insight into the mechanism of magnetism.

Chlorosis in Tomatoes

IN the west of Scotland, chlorosis of the leaves of tomato plants has been widespread during the past season and has been investigated at the West of Scotland Agricultural College, Auchincruive, Ayr.

Abnormal leaves of affected plants showed a characteristic appearance; the vascular system with a strip of adjacent lamina and the leaf margins remained green while the interveinal areas became a bright yellow colour (sometimes greenish-yellow).

In extreme cases the margins of the leaf also lost their chlorophyll, but the vascular system and adjacent lamina were not observed to lose chlorophyll under normal conditions of cultivation.

The chlorosis appeared first as small yellowish-green areas in the interveinal tissues and the leaves eventually became brittle and tended to die prematurely. The leaves immediately above the third truss were the most affected. Chlorotic plants produced less fruit on the upper trusses than did normal plants, and although unaltered in flavour, the fruit was smaller than usual. The composition of the lamina of normal and chlorotic leaves is given in the appended table and it is clear that the amount of magnesium in the chlorotic lamina is less than that in the normal.

COMPOSITION OF THE LAMINA OF NORMAL AND CHLOROTIC LEAVES.

	Dry matter %	Ash % in dry matter	Ash % in original	Nitrogen % in dry matter	Nitrogen % in original	P_2O_5 % in dry matter	P_2O_5 % in original
Normal lamina	13·25	27·32	3·62	0·046	0·0061	1·38	0·18
Chlorotic lamina	13·05	22·75	2·97	0·036	0·0048	0·82	0·11

	K_2O % in dry matter	K_2O % in original	CaO % in dry matter	CaO % in original	MgO % in dry matter	MgO % in original
Normal lamina	5·45	0·72	9·07	1·20	0·43	0·056
Chlorotic lamina	6·34	0·83	6·21	0·81	0·10	0·013

With regard to the factors causing the chlorosis it was observed that only plants bearing a large amount of fruit on the first few trusses were chlorotic, although all such heavy bearing plants were not affected. It was seen also that the chlorosis usually appeared when the fruit of the first three trusses was almost fully developed, that is about the first week of June, and at that time the plants were still growing vigorously. The leaves produced by the plants in the latter part of the season, when yields were fairly small and active growth much diminished, were not chlorotic. It would seem, therefore, that the chlorosis is the result of extensive physiological drain to a large maturing crop of fruit and to actively developing leaves.

In our opinion the chlorosis is due to a deficiency of magnesium, although it should be borne in mind that the relatively small amount of magnesium in the lamina of abnormal leaves may be the result, and not the cause, of the chlorosis. That the chlorosis is a result of magnesium-deficiency is supported by the similarity between the chlorotic plants and plants which were grown in magnesium-deficient sand cultures, and by the comparable symptoms of naturally occurring magnesium-deficiency diseases of tobacco, potato and other plants. The amounts of replaceable magnesium were estimated in soils in which chlorotic plants were growing and the values obtained were high. The chlorosis, therefore, does not appear to be due to a deficiency of magnesium in the soil but rather to the plants being unable to absorb sufficient when the physiological demand is great.

Poor root action also appeared to play a part in the production of the chlorosis. This was indicated by the chlorosis often being associated with the presence of root rot fungi, poor physical condition of the soil and low soil temperature, all of which would reduce the ability of the plants to absorb magnesium.

Attempts were made to control the chlorosis by injecting solutions of magnesium salts but results were not satisfactory, although the injections did improve the condition of the chlorotic leaves to a slight extent. Further, chlorotic and normal leaves were rooted in sand and watered with culture solutions containing various ratios of potassium and magnesium, and with solutions free from these elements. These leaves remained in sand culture for three months and observations made during this period indicated that the chlorotic condition was associated with low magnesium and apparently also with a high potassium – magnesium ratio. The view that the absorption of magnesium is closely connected with the potassium – magnesium ratio in a culture or soil solution receives support from several sources. D. D. Brown[1] in his work on wheat showed that high concentrations of potassium in sand cultures reduced the amount of magnesium absorbed by the plants. Also, many workers have shown that when the concentration of potassium in soils and culture solutions is low, plants tend to accumulate magnesium. Further, the soils in the west of Scotland in which the chlorosis appeared showed a very high concentration of potassium (0·1–0·3 per cent K_2O often being present), and soils containing less potash tended to produce healthy plants, always provided that the other growth factors were satisfactory.

It is interesting to note that the chlorosis appeared on soils having widely divergent *p*H values and that it was not influenced by liming.

The conclusion reached is that the chlorosis is due to a temporary deficiency of magnesium in the leaves resulting from physiological drain of the available magnesium from mature leaves to fruit and immature leaves. Poor root action and lack of balance between potassium and magnesium ions in the soil appear to be contributory causes.

Determination of Moisture Content

THE recent communication[1] on this subject prompts me to describe more fully a method for moisture determinations that was mentioned in an earlier letter[2].

The method as applied to a variety of substances used in confectionery manufacture consists of "mixing a suitable quantity (usually 5 grams) of material (warmed in the case of syrups, to reduce the viscosity) with an approximately equal weight of absolute alcohol, followed by five hours drying at 105° C. in a well ventilated oven." At this temperature decomposition, as shown by darkening, is slight even with acid sugar-containing substances. Slight increases in temperature above 105° C. greatly increase the amount of decomposition. The method gives reproducible results, and while after five hours absolute constancy of weight is not attained, losses after this period are very slight. The method is clearly not applicable to living plants or animals, as the nature of the material often prevents rapid and intimate mixing with the alcohol. For powdered material it appears an admirable method, especially for routine work when some fairly rapid, but not time-consuming, method is needed.

This method of moisture determination was introduced to me by Mr. H. R. Jensen.

The Saqqara Graph

SINCE my communication published in NATURE of October 17, p. 460, an excellent example of an ancient Egyptian arch has come to hand in Plate 17 of Glanville's "Legacy of Egypt"[1], a photographic print of an imitation of matting in faience and stone on a panel from a gallery in the Step Pyramid at Saqqara. On testing the upper arc of this arch, I find that it is undoubtedly developed from a 5-unit circle in the way I suggested for the arch of the Saqqara graph.

Taking the height of the arc in the plate as 22¾ mm. ($= aX = 2$ units), the base, YXY, of the parent circular arc is 91 mm., and the radius 56⅞ mm. Erect twelve ordinates, 7 mm. apart, on YY, and then ordinates of the same height, but 8 mm. apart, on a base of 104 mm. The resulting segment is practically identical with that of the plate, the ordinates coinciding with the pillars of the arch.

This illustration of the use of the 3–4–5 right-angled triangle as a basis of arch construction is convincing, since the arch provides the evidential measurements. It comes from the same place, Saqqara, as the graph, and is of the same period, being variously ascribed to the IIIrd or IVth Dynasty.

Role of Protozoa in the Activated Sludge Process

VARIATIONS in the biological activity of activated sludges have been ascribed to a number of causes, and attempts have been made to relate the presence of characteristic organisms to the activity of the sludge. Reynoldson[1] found that under the conditions existing at the Huddersfield Sewage Works, the logarithm of the Vorticella count in the activated sludge closely followed its biological activity, as measured by the purity of the effluents produced.

Pillai and Subrahmanyan[2] claim that the ciliate Epistylis is not only of paramount importance in influencing the actual oxidative processes performed by activated sludge, but also that it surpasses all other organisms in its ability to cause flocculation. It is worth noting that flocculation may be responsible for 40 per cent of the total purification effected by the sludge[3].

Examination of various types of activated sludge, produced under different conditions, lead me to conclude that the scanty knowledge available of the nutrition and development of Protozoa in activated sludge does not justify sweeping generalizations relating the protozoan count to biological activity. One activated sludge which has produced effluents of uniform composition over a period of many months sometimes contains relatively few classes of Protozoa, with a species of Epistylis preponderating, whereas at other times the protozoan fauna has been completely dominated by Paramecium, in numbers so great as to form 5 per cent or more of the bulk of the sludge. However, flocculation and oxidation proceed satisfactorily in the absence of Protozoa. It is still possible that the Protozoa play an important part in maintaining bacterial activity at a high level, but this has yet to be proved to occur in activated sludge.

The point I wish to make is that there is ample scope for a systematic study of the protozoan fauna of activated sludge, and its influence on the activity of the sludge.

RESEARCH ITEMS

Heterogeneity in Wheat Germ and High B_1 White Flour

In a paper "The Vitamin B_1 and Riboflavin Contents of Wheat Germ" just published (*Chem and Ind.*, September 1942), J. J. C. Hinton has shown that the two fractions of wheat germ, scutellum and embryo, differ in physical properties. More important is the fact that their B_1 contents are very different, that of the scutellum averaging 40 I.U. per gram and of the embryo 4 I.U. per gram. The riboflavin values, on the other hand, are roughly constant at 15 γ per gm. This work is of fundamental importance in flour milling, and T. Moran in an article published in *Milling* (October 10, 1942), has shown its application to Canada-approved white flour and high B_1 white flours generally. Nutritionally the ideal white flour would appear to be one containing the full amount, roughly 1½ per cent, of scutellum; the precise milling procedure necessary to obtain such a flour is a pretty problem in milling engineering. In dry milling, such as is now general practice in the milling of National flour, the scutellum adheres tenaciously to the adjoining endosperm and, therefore, probably finds its way into the finished meal. This is the explanation of the relatively high B_1, averaging 1·10 I.U. per gram, value of National flour.

Integument of Insects and the Entry of Contact Poisons

V. B. Wigglesworth has recently published the results of some interesting work on this subject (*Bull. Entom. Res.*, 33, 205–218; 1942). He deals in particular with certain structural and physiological features of insect cuticle and their relation to the entry of contact insecticides—in special extracts of pyrethrum in oil. It is found that, as a rule, insects immersed in oils exude minute droplets of water over the surface of the cuticle. Factors governing the rate of entry of pyrethrum through the cuticle have been studied by the application of this substance in oil to a restricted area of the abdomen of the bug Rhodnius. Entry is more rapid in light than in heavy petroleum oils, but is very slow in vegetable oils. There are great individual variations, due chiefly to the thickness of the endocuticle and other factors. There is also evidence that the pore canals are important in connexion with the passage of pyrethrum through the endocuticle. Histological examination of the integument shows that, in the nymphs of Rhodnius, oils are first taken up by the epidermal cells around bristles and later by the general epidermis. The uptake of oil is much increased by adding 5 per cent of oleic acid to refined petroleum. Among adult Rhodnius, soon after ecdysis, oils are taken up by the general epidermis, whereas in old insects they are taken up only by the dermal glands.

Parthenocarpy Induced by Frost in Pears

The occurrence of frost when fruit trees are in bloom is generally regarded as detrimental if not disastrous. However, D. Lewis (*J. Pom. and Hort. Sci.*, 20, 40; 1942) has shown that in some cases it may be instrumental in producing a crop. Among pear varieties, Conference and Fertility are usually regarded by growers as self-fertile, but indoor tests at the John Innes Horticultural Institution have shown them to be highly self-sterile. Outdoor tests under isolated conditions, on the other hand, resulted in the production of fruits by both varieties after self-pollination. The Fertility fruits were seedless whereas those of Conference dropped before full maturity. It was noticed that the styles of many of the flowers of the outdoor trees were blackened by frost at the time of pollination and it seemed likely that parthenocarpic fruits had been developed by the action of cold. This hypothesis was tested by keeping individual branches of potted trees at low temperatures from 0° C. to −9° C. for varying periods. Out of nineteen flowers kept at −9° C. for 18 hours, nine swollen fruits were produced, of which two reached maturity. These were good, well-shaped specimens, but contained no seeds and only traces of ovules. At other temperatures many fruits were produced but dropped in June before reaching maturity. It is concluded that cold stimulation may play a great part in maintaining regular bearing in some pear varieties. In a cold spring in which insects are not active to effect cross-pollination, a frost at the time of flowering, instead of doing damage, may be the making of a good crop.

Volatile Products from Apples

Ethyl alcohol, acetylene and ethylene are among the volatile substances known to be evolved from ripening apples. The latter is of considerable commercial importance because of its ability to initiate ripening in green fruits and cause injury to the skin of ripe apples. Other substances as yet unidentified are presumed responsible for the appearance of 'scald'. L. P. Walls (*J. Pom. and Hort. Sci.*, **20**, 59; 1942) has improved on the current methods of estimating these volatile products by using sulphuric acid, activated by the addition of 2 gm. silver sulphate per 100 ml. as an absorbing agent. Preliminary tests with a stream of air containing ethylene (1 in 10,000) showed that more than 90 per cent of the ethylene was absorbed. The condensable and odorous products from King Edward VII and Laxton's Superb apples were absorbed in a preliminary trap of ordinary sulphuric acid, which accounted for about one third of the total volatile products. Most of the remaining two thirds was absorbed in a second trap containing activated acid. This acid reacted quantitatively with chromic acid giving acetic acid in amounts agreeing with the assumption that the bulk of the absorbed substance was ethylene. It is concluded, therefore, that ethylene forms a high proportion of the volatile substances produced during the storage life of the apple. By the use of adsorbents, the production of volatile substances more readily condensable than ethylene and of possible importance in relation to scald was confirmed. Among these the acetic and formic esters of amyl alcohol were identified.

Auxin and Leaf-Protein

A number of hypotheses have been advanced concerning the substances from which auxin is released in the plant. S. G. Wildman and S. A. Gordon (*Proc. Nat. Acad. Sci.*, 28, 217; 1942) have shown that proteolytic enzymes release auxin from the proteins in the leaf of spinach. Proteins from both cytoplasm and from the chloroplasts release auxin after enzymatic hydrolysis by tryptic extract, trypsin and chymotrypsin. Papain produced little hydrolysis at *p*H 4 or 6. Diffusion experiments indicate that leaf auxins and the auxins released from the protein of the leaf are similar and of lower molecular weight than indol-acetic acid.

Systematics of Polychæta

OLGA HARTMAN has examined critically fifty type specimens of Polychæta in the United States National Museum ("The Identity of some Marine Annelid Worms in the United States National Museum", *Proc. United States Nat. Mus.*, 92; 1942). The species have been minutely examined, and emended descriptions are given in most cases. Among these type specimens is *Phyllodoce fragilis* Webster, and it is interesting to learn that the author has collected this species frequently at Beaufort, N.C., where it has a tendency to mass together in the interstices of oyster clumps. One new species is proposed, *Lumbriconereis moorei*, for two fragmentary specimens allied to, but not identical with, *L. minuscula* Moore. These occurred in 1,350–2,182 fathoms off Catalina Island and possess greatly elongated setæ in the anterior segments—a characteristic apparently of certain deep-water forms, or, possibly, of a unique type of substratum. Most of those with this particular feature occur on blue mud. E. and C. Berkeley publish a list of Polychæta collected at the northern extremity of the west coast of North America ("North Pacific Polychæta, chiefly from the West Coast of Vancouver Island, Alaska and Bering Sea", *Canad. J. Res.*, 20, No. 7; July 1942). There are interesting remarks connected with some of the species. Observations on *Phyllochætopterus prolifica* Potts confirm Potts's own supposition that although he observed no individuals with sexual products (having described in some detail the process of asexual reproduction) this was probably due to insufficient examination. The present work shows that mature individuals of both sexes have frequently been found in tubes. There are four new species in this collection, including two of Pista, *P. pacifica* and *P. moorei*.

Mycological Taxonomy

A STUDY of type species of agaricaceous genera by Rolf Singer (*Lloydia*, 5, No. 2; June 1942) utilizes modern conceptions of the presence of clamp connexions in hyphæ, and the presence of starch or other substances in spores, as practical diagnostic characters even in old, dried herbarium specimens. Most of the types studied are peculiarly American, but the British mycologist can obtain useful ideas on taxonomy in general, for several keys to small groups of genera are given, upon the above criteria. Fifty-two new species of fungi from Florida are described in the same number of *Lloydia* by Wm. A. Murrill. These are named according to American groups, but are mainly included under Saccardo's genera Psathyra, Panæolus, Galera, Tricholoma, Clitopilus, Volvaria, Hygrophorus and Collybia.

Cultivation of Derris in India

THE main toxic constituent of derris is rotenone, but along with it are several other related toxic substances. These substances have, hitherto, been found to occur in only a few species of plants belonging to the natural order Leguminosæ. T. P. Ghose in a communication entitled "A note on *Derris* and other Rotenone Bearing Vegetable Insecticides, their Occurrence and Possibilities of Cultivation in India", has discussed this subject (*Indian Forest Leaflet*, No. 20 (Chemistry). Forest Research Institute, Dehra Dun, 1942). It appears that search for such rotenone-bearing insecticides has resulted in the discovery of rotenone in the following plants that are indigenous to India: *Derris ferruginea*, *Millettia pachycarpa* and *Tephrosia candida*. The existing material is sufficiently rich for the preparation of efficient fluid or powder insecticides. It is suggested that by selection of suitable strains and by proper cultivation it may be possible to improve the rotenone content of the above mentioned species. Furthermore, several localities in India have suitable climatic and soil conditions to warrant the introduction and cultivation of richer varieties of commercial derris such as *Derris elliptica* or *D. malaccensis* indigenous to Malaya. Experiments have been carried out that yielded encouraging results in Mysore, Cochin and Assam.

Copper-bearing Protein in Cow's Milk

THE presence of copper in tissues is known to be essential for the formation of hæmic iron in animals and to play a part in the form of copper proteins as oxidases in plants. The presence in animal tissues of a non-hæmin iron associated with copper as a copper-iron nucleoprotein is reported. Cow's milk contains 0·09–0·17 mgm. of copper per lit., and W. L. Dills and J. M. Nelson (*J. Amer. Chem. Soc.*, 64, 1616; 1942) isolated from it a protein containing about 15 per cent of nitrogen and 0·19 per cent of copper. Dialysis showed that the copper was non-ionic. Enzymatic activity was not found either in relation to ascorbic acid oxidase activity or polyphenolase activity.

Ester Hydrolysis

THE reactions between tertiary butyl and benzyl nitrates with water and hydroxyl ion differ; in the first case, hydrolyses to alcohol and to olefin occur:

$$C_4H_9ONO_2 + 2H_2O = C_4H_9OH + H_3O^{\cdot} + NO_3' \qquad (A)$$

$$C_4H_9ONO_2 + H_2O = C_4H_8 + H_3O^{\cdot} + NO_3', \qquad (B)$$

whilst in the second no olefin is produced but the alcohol-forming reaction is accompanied by a first order reaction giving benzaldehyde and nitrous acid:

$$C_6H_5CH_2ONO_2 + 2H_2O = C_6H_5CH_2OH + H_3O^{\cdot} + NO_3' \qquad (C)$$

$$C_6H_5CH_2ONO_2 = C_6H_5CHO + HNO_2; \qquad (D)$$

and second order reactions with hydroxyl ion:

$$C_6H_5CH_2ONO_2 + OH' = C_6H_5CH_2OH + NO_3' \qquad (E)$$

$$C_6H_5CH_2ONO_2 + OH' = C_6H_5CHO + H_2O + NO_2' \qquad (F)$$

G. R. Lucas and L. P. Hammett (*J. Amer. Chem. Soc.*, 64, 1928; 1942) show that the kinetics of the reactions strongly indicate identical mechanisms for the *t*-butyl nitrate and halides, the latter previously investigated by Ingold and collaborators (*J. Chem. Soc.*, 925, 960 f.; 1940). No appreciable reaction with hydroxyl ion or catalysis by acids was observed. It is shown that perchlorate ion accelerates the reaction but hydroxyl ion retards it, and other ions have intermediate effects which parallel their effects on the activity of water in the medium. This materially weakens a kinetic argument previously used for a free carbonium ion intermediate in hydrolytic reactions. The kinetics of hydrolysis of benzyl nitrate to benzyl alcohol suggests that the reaction partakes more largely of true hydrolysis rather than displacement of anion by a water molecule than does that of the halide. There is pronounced acceleration by hydroxyl ion but acids have no effect. These results suggest that the explanation of the mechanism of ester hydrolysis is less final than has recently been supposed.

INSECT FAUNA OF A BRINE-PIT

By FREDERICK BURKE

THE brine-pit[1] described is apparently a disused well from which brine was formerly pumped (Fig. 1). It is situated on the south side of Wych-brook, the boundary between Cheshire and Flintshire (detached), and about two miles south of Malpas. The pit is roughly circular in shape with an approximate diameter of 25 ft. According to Ormerod[2], it was sunk through clay to the depth of 450 ft., or 300 ft. below sea-level. In May 1941, during a preliminary visit, numerous dipterous larvæ and pupæ were discovered in the pit water. Analysis of the water, at that time, showed a salinity of 9,400 parts per 100,000. So far as can be ascertained, little attention appears to have been directed, in Great Britain, to the insects inhabiting pools of high salinity such as are to be found in parts of Cheshire. Pending a more detailed account, therefore, the following notes have been compiled from observations made over a period May 1941—August 1942 inclusive. During this period the pit has been visited on nine occasions.

TABLE 1.

Date of sampling	*p*H value (Lovibond comparator)	Sodium chloride Parts per 100,000	Total salts Parts per 100,000
18/5/41	7·2	9,400	— †
15/6/41	6·4	9,500	10,200
20/7/41	7·8	9,100	— †
31/8/41	8·7	9,100	— †
12/10/41	8·0	7,900*	8,500
14/12/41	8·0	8,000*	8,800
2/5/42	6·5	9,400	10,300
21/6/42	7·5	9,500	10,400
16/8/42	8·5	9,400	10,300

* Samples collected after a period of very wet weather.
† Undetermined.

TABLE 2.

Depth	*p*H value (Lovibond comparator)	Sodium chloride Parts per 100,000	Total salts Parts per 100,000
Surface	8·5	9,400	10,300
10 ft.	7·0	9,300	10,200
20 ft.	6·5	9,300	10,200
30 ft.	6·5	9,300	10,200

Analytical values for surface samples of water collected at each visit are given in Table 1. Values for samples collected with a Meyer's bottle[3] from 10, 20 and 30 ft. below the surface of the pit are given in Table 2. These tables present a general picture of the environmental conditions existing at the pit. It will be seen that throughout the period indicated the water has maintained a fairly constant salinity, although slight variations occur depending on the rainfall and on the amount of evaporation which takes place.

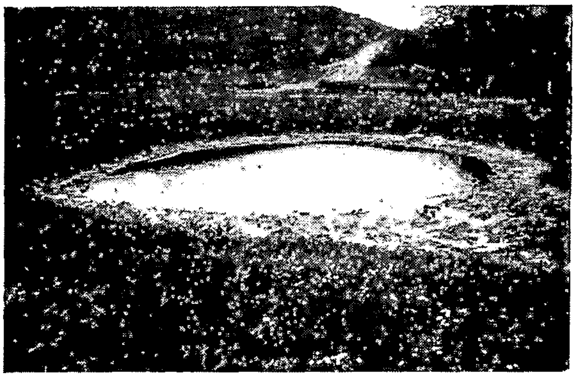

Fig. 1. THE BRINE-PIT, MALPAS.

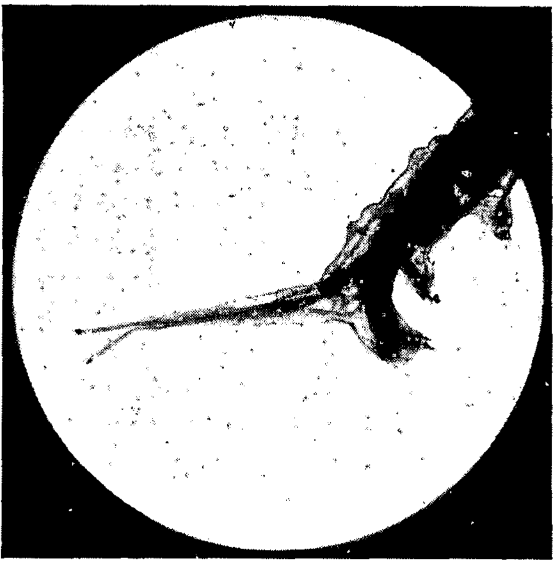

Fig. 2. LARVA OF *Ephydra riparia*, SHOWING RETRACTABLE SPIRACLES AND HOOKED SEGMENT. × 12.

The following insects have been identified from the pit:

Ephydra riparia Fallén (Diptera) is the predominating insect breeding in the pit and it occurs in very large numbers. The larva is remarkable for its interesting forked tail which carries two retractable spiracles (see accompanying photograph). In addition, it possesses a curious hooked segment, on the back near the end of the abdomen, with which it attaches itself to pieces of twig and similar objects at the time of pupation. *Ephydra riparia* belongs to the family Ephydridæ, a group of insects which appears to be particularly well adapted to life in a variety of unusual habitats. Carpenter[4] states that all species of Ephydra are capable of living in high concentrations of salt. Several species have been recorded by Thorpe[5] from brackish pools on the Sussex coast. It is interesting to note also that the petroleum pools of California are inhabited by the larva of a fly described by Thorpe[6] as a member of this family.

The specimens of *Ephydra riparia* which have been collected from Malpas brine-pit were highly parasitized by a small chalcid (Hymenoptera) belonging to the family Pteromalidæ. Many of the species of this group are at present undetermined and in consequence this parasite unfortunately remains unidentified.

Nemotelus notatus Zett. (Stratiomyiidæ) is another dipteron recorded breeding in fairly large numbers in the shallow water around the pit edge. The larva, when not crawling over the mud, has a curious habit of remaining submerged in shallow pools with a bubble of air attached to its posterior spiracles. Larvæ, pupæ and perfect insects of Nemotelus have been collected from time to time. Thorpe[5] records a species of Nemotelus from the Sussex coast.

Pupæ of the dipteron *Atissa pygmæa* Haliday were first observed at the pit on August 31, 1941. Only one perfect insect, however, emerged on September 1, 1941, from those pupæ which were collected. *Atissa pygmæa* was seen on frequent occasions during later visits to the pit, but it was never found in any great numbers.

From the observations here recorded it is interesting to note that the insects found in such an unpromising environment are all members of the Diptera. In this connexion it is perhaps well to repeat the statement made by Thorpe[7] that "the Diptera are not only able to support life in media of an osmotic pressure that is rapidly fatal to most other insects, but that they have also a greater power of adaptation to changes in concentration than have other orders".

In concluding this brief account of the insects inhabiting the brine-pit, mention should perhaps be made of those insects which from time to time have been discovered in the pit water but do not actually breed in the brine. On several occasions the hemipteron Corixa (species undetermined) was observed to visit the pit and swim for short periods in the water. On August 31, 1941, the beetle *Ilybius fuliginosus* F. was captured while swimming in the water. On June 21, 1942, an unidentified Hydrobius larva was taken when collecting water samples.

It is a pleasure to record here my acknowledgement of the assistance given by Mr. Riley, Mr. Coe and Mr. Donisthorpe of the British Museum, and of Mr. H. Britten of Manchester, in the identification of the insects found. I wish also to thank Mrs. Kay of Brine-pits Farm, Malpas, for permission granted to visit the pit; and finally to my wife for help in collecting.

WAR-TIME TRANSPORT IN GREAT BRITAIN

THE Fifteenth Report of the Select Committee on National Expenditure demonstrates the vital importance of transport to the war effort of Great Britain. That bad transport is one of the main causes of absenteeism and lost time in production has been emphasized from time to time in the Select Committee's earlier reports, and the evidence received during the last six months led the Committee to make a special investigation into this problem from the side of the Ministry of War Transport and the transport undertakings. While this aspect of the problem is fairly generally appreciated, it is intimately if not inseparably linked with that of passenger transport generally, and the full extent of the repercussions of the rubber and petrol situation are very far from being realized by the general public.

The evidence submitted to the Select Committee indicates that there are few, if any, services running which are not essential. The recent restrictions on the use of motor-cars in Great Britain render buses more than ever necessary for meeting the needs of the general public. Even in non-industrial areas, there is already a shortage, and there, as elsewhere, intending passengers are frequently left behind. The priority system is only partly effective in securing the transport of industrial workers. It is open to abuse, and the practical impossibility of distinguishing between essential and non-essential passengers is one of the first factors in the situation to which regard must be paid.

The second factor, which is by no means fully recognized, is the effect which transport restrictions have already had on industrial efficiency. There is a serious handicap, for example, on management, because it is no longer possible to choose the quickest and most efficient means of transport. Economy in petrol often means waste in man-hours. Moreover, not only is output affected in the factories if workers and management cannot arrive in time but also, as the Select Committee points out, the morale of the country will be affected if the housewife cannot do her shopping or if her child cannot get to and from school. It might well be added that workers in the larger towns, with their longer hours in a heavily polluted atmosphere, will suffer in health and their work in efficiency if transport restrictions deprive them entirely of access to fresh air and the countryside. No long-term policy of planning the war, such as we should now be pursuing, can safely disregard such considerations, and the severer the limitations of transport the more essential it becomes to plan their use to the maximum extent.

Transport, in fact, occupies a key place not only in the production of munitions, but also in the daily life of every man, woman and child in Great Britain. The vital importance of transport must be kept constantly in mind when questions of priority of labour and materials are decided. Indeed, the Select Committee is not merely concerned with the fair and efficient use of existing facilities; it also gives frank warning that it may well be essential to increase those facilities, and reference is made in particular to provision for the manufacture of buses and spare parts and for the supply of fuel and tyres.

What emerges from this survey is the importance of securing full co-operation between the transport services themselves and the general public which uses those services. One of the major difficulties is the labour shortage, which is aggravated by a high percentage of absenteeism among women workers, and the Ministry is criticized for its neglect to make any serious effort to ascertain the causes of such absenteeism.

Many of the Committee's suggestions are on points of practical detail. In regard to the difficult question of staggering hours in shops or factories, it recommends the establishment of local transport consultative committees in all areas and the introduction of schemes for internal or general staggering of factory hours. When such schemes are being worked out, the factories affected should be grouped roughly according to the priority of their products, so that some attempt may be made to allot the best time to the most important factories. Regional commissioners in all regions should make orders enforcing the early closing of shops in the central shopping sites of large cities, so that both shop-workers and customers can be got home before the rush of factory workers begins, and employers should, where necessary, make arrangements that their employees get reasonable shopping facilities during these restricted times. Similarly, it is recommended that except in emergency, factory hours should not be altered without first considering the transport problems involved, and the local transport consultative committees should be fully used for such purposes.

If, however, the public themselves are to help to improve the transport services of Great Britain, much greater publicity must be given to the reasons for transport difficulties. "Transport goes to War", recently issued by the Ministry of Information, makes a beginning although the emphasis is rather excessively on the blitz conditions and effects : what is wanted is something to grip the public imagination and secure their support and sympathy under everyday war-time conditions. Moreover, any appeal for the co-operation of the public, such as the Select Committee suggests, must be based not merely on a fuller understanding of the difficulties of the transport services themselves, but also on a sympathetic appreciation of the position and difficulties of the travelling public. The importance of diverting more traffic from the roads to the railways is stressed, and it is recommended that where adequate railway facilities are available for any particular factory or group of factories, special bus facilities should not be provided. Similarly, the natural tendency for people to rush for the last bus which gets them to their work at the right time requires correction by individual response, but apart from an examination by the Ministry of Labour of the possibility of reducing cross-travelling between one town and another by directing workers to places nearer their homes, it may well be doubted whether there is much unnecessary travelling by train on the part of the general public, at least over distances of any extent. It is clear from this report that the point has been reached, if not passed, when a further reduction in travelling facilities, whether by bus or rail, is likely to be a false economy, and to impair the war effort to an extent more rather than less serious, because the waste of time, of labour or of health that results may be indirect and cumulative rather than immediately obvious.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Saturday, November 21

ROYAL PHOTOGRAPHIC SOCIETY (SCIENTIFIC AND TECHNICAL GROUP) (at 16 Princes Gate, South Kensington, London, S.W.7), at 2.30 p.m.—Symposium on "Industrial Radiography".

Monday, November 23

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. A. C. Pallot : "Some Aspects of Insulation", 1 : "Thermal Insulation at Medium Temperatures—The Insulation of Pipes and Structures" (Cantor Lectures, 1).

BRITISH COUNCIL, ROYAL ASIATIC SOCIETY, EAST INDIA ASSOCIATION AND THE INDIA SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 3 p.m.—Mr. Laurence Binyon : Fourth Centenary of the Mughal Akbar.

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5 p.m.—Kodachrome Film : "Halifax to Victoria B.C." ; Commentary by Mr. C. W. Stokes.

Tuesday, November 24

CHADWICK PUBLIC LECTURE (in the Sir Edward Meyerstein Lecture Theatre, Westminster Hospital Medical School, 17 Horseferry Road, London, S.W.1), at 2.30 p.m.—Sir Arthur MacNalty, K.C.B. : "The Prevention of Tuberculosis in Peace and War".*

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 3 p.m.—Prof. J. C. Drummond : "The History of our More Important Foods", (i) Bread.*

INSTITUTION OF CIVIL ENGINEERS (ROAD ENGINEERING DIVISION) (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Mr. A. H. D. Markwick and Mr. H. S. Keep : "The Construction of Bases for Roads and Aerodromes using Local Aggregates and Soils".

ASSOCIATION OF SCIENTIFIC WORKERS (at the Royal Photographic Society, 16 Princes Gate, South Kensington, London, S.W.7), at 6.30 p.m.—Projection of the Cine Films entered for the Exhibition of "Photography in Science and Industry".

Wednesday, November 25

INSTITUTE OF PHYSICS (ELECTRONICS GROUP) (at the Royal Inst tution, Albemarle Street, London, W.1), at 3 p.m.—Mr. G. T. Winch "Photo Cells and their Applications".

Friday, November 27

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), a 5 p.m.—Mr. Frank Twyman, F.R.S. : "Interferometry in the Optica Workshop".

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDER (in the Lecture Theatre of the Mining Institute, Newcastle-upon-Tyne) at 6 p.m.—Mr. R. C. Thompson and Mr. Harry Hunter : "The Britis Merchant Shipbuilding Programme in North America, 1940–42' (Andrew Laing Lecture).

Saturday, November 28

ROYAL PHOTOGRAPHIC SOCIETY (at 16 Princes Gate, South Kensington, London, S.W.7), at 3 p.m.—Dr. S. O. Rawling : "Sensitometry since Hurter and Driffield" (Hurter and Driffield Memoria Lecture).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on o before the dates mentioned :

LECTURER IN ENGINEERING SUBJECTS—The Principal, Kingsto Technical College, Kingston, Surrey (November 28).

VISITING MATHEMATICS LECTURER—The Principal, Froebel Educational Institute, Knebworth House, Knebworth, Herts (December 1)

LECTURER IN MECHANICAL ENGINEERING at the Rugby College o Technology and Arts—Mr. P. I. Kitchen, Organizer of Furthe Education, Rugby (December 2).

INSTRUCTOR IN BEEKEEPING—The Education Officer, County Hall, Wakefield (December 14).

REGIUS PROFESSOR OF GEOLOGY at Edinburgh University—The Private Secretary, Scottish Office, Fielden House, 10 Great College Street, London, S.W.1 (January 11).

ASSISTANT TECHNICIAN IN THE PATHOLOGICAL DEPARTMENT—The Superintendent, Grimsby and District General Hospital, Grimsby.

ANGLO-AMERICAN RELATIONS IN RECONSTRUCTION

THERE can be few who would not agree as to the importance of intimate co-operation between the United States and Great Britain both in winning the war and in winning the peace, though there are clearly some who are dubious as to the feasibility or durability of that co-operation. The agreement between Great Britain and the United States signed last February, and the exchange of notes during September on the principles applying to mutual aid and to reciprocal aid, set forth some of the ways and means by which this essential co-operation may be made effective.

As Mr. Harold Butler has pointed out in an article in *Agenda*, written before he left for Washington to take charge of British information services there, the far-reaching importance of these latter documents has scarcely been generally realized. In particular, the enumeration in Article 7 of the Agreement of February 23 of the principles upon which a settlement of the Lease-Lend account is ultimately to be concluded, which is the essential part of the agreement, has been commonly overlooked. The subsequent exchange of notes detailing the terms on which war supplies and services are to be exchanged, carrying the lease-lend policy a stage further, tends to divert attention yet more from these principles. Yet it is all to the good that this latter document should make it so plain that lease-lend supplies have long ceased to be a one-way traffic eastwards across the Atlantic. There has been considerable exchange of scientific information, but it is to be regretted that the censorship in the United States has operated in such a way as to delay or prevent the transmission abroad of a journal such as *Science* and of individual articles in other scientific journals, thereby impeding the flow of information.

There can be no question as to the soundness of laying down so far as possible the principles upon which reciprocal aid is applied in the prosecution of the War. That is one of the surest methods of eliminating misunderstandings or any friction which may be engendered by arbitrary or injudicious handling either of the censorship or other matters. We may count on Mr. Butler to continue in Washington that invaluable work of interpretation and exposition to which he addressed himself in Great Britain.

The principles upon which a final settlement is to be concluded may be briefly summarized as follows: First, the terms "shall be such as not to burden commerce between the two countries". Secondly, their aim is not merely the promotion of Anglo-American trade, but also "the betterment of world-wide economic relations". Thirdly, the methods by which this goal is to be sought are: (*a*) through "the expansion, by appropriate international and domestic measures, of production, employment, and the exchange and consumption of goods"; (*b*) through "the elimination of all forms of discriminating treatment in international commerce"; and (*c*) through "the reduction of tariffs and other trade barriers". Fourthly, participation in agreements to this end shall be open to "all other countries of like mind".

Mr. Butler considers that this agreed statement of aims may prove a decisive factor in the development of Anglo-American relations. Agreement in the view that the key to a comprehensive economic settlement is to be sought in an expansionist policy immensely facilitates the discussion of the thorny problems which will have to be solved. A big step has been taken towards assuring the co-operation of the two countries during the difficult period of international reconstruction. Great Britain and the United States are pledged to a joint effort in building a new world economy. The major responsibility in European restoration must indeed fall on Great Britain, but we cannot give the lead and secure the co-operation of our allies, and not least of the Soviet Union, without thinking on an international scale and creating international machinery.

These agreements pledging Britain and the United States to work together with a common plan and a common ideal provide us with the means of forging a powerful weapon in the war of ideals. As the outline of a better society begins to take shape, holding the promise not only of national freedom and individual liberty, but also of greater social security based on economic prosperity, the United Nations will fight with redoubled energy. The Anglo-American agreements may well be developed into the programme of a new international order, adding fresh driving force to the faith of the United Nations ; and the remarkable series of speeches in recent months by leading men of the American administration, from the President downwards, shows the extent to which a new idealism has already gripped the minds not only of economists, sociologists and scholars, but also of statesmen. Mr. Henry Wallace's thought of "the century of the common man" rather than of "the American century" has clearly caught the imagination on both sides of the Atlantic.

These speeches of Mr. Wallace, Mr. Sumner Welles and Mr. Cordell Hull are of importance as indicating the beliefs upon which the American conception of a new order rests. Mr. Hull indeed has laid down the principles of a broad programme of world economic reconstruction in direct opposition to the programme outlined by the Nazis, and it pre-supposes an attempt to combine economic liberty with economic order. He repudiates excessive trade restrictions or discrimination in international commercial relations. Raw materials must be available to all nations without discrimination. International agreements regulating the supply of commodities must be handled so as to protect fully the interests of the consuming countries and their peoples. The institutions and arrangements of international finance must be set up so that they lend aid to the essential enterprises and continuous development of all countries, and promote the payment through processes of trade consonant with the welfare of all countries.

This programme and these principles have far-reaching implications, including the condemnation of past trade policies of Great Britain and of the United States. It will be noted how far in harmony they are with the new colonial development policy which has been initiated since the outbreak of war, and with the outlook on this topic of Lord Hailey and others in Great Britain. What must be realized, however, is the importance of the American approach and the American proposals being clearly understood in Great Britain. As Mr. Butler says truly, the active prosecution of British thought on reconstruction is a war-issue as well as a peace-issue.

Neither in the United States nor in Britain, in fact, can our thought about reconstruction, whether internal or international, be confined to purely national considerations or calculations. Naturally enough, much more thinking on post-war problems has been done during the last two years in the United States, but the concern which Lord Reith and, more recently, Lord Latham have expressed in the House of Lords at Government delay in dealing with the findings of the Scott and Uthwatt Committees, and in providing the essential machinery for planning, is not entirely a domestic issue. It inspires criticism abroad which may not always be fair, but such dilatoriness towards planning is a handicap to good Anglo-American relations, as is very clear from Mr. Butler's article.

The debate in the House of Lords on November 18 and 19 arose out of a motion by Lord Latham urging the Government to introduce without delay the legislation necessary to make possible preparatory steps, so that actual planning and reconstruction may begin as soon as hostilities cease, and referred only to reconstruction in Great Britain. It produced statements from Lord Portal, Minister of Works and Planning, and the Lord Chancellor, respectively, the tenor of which was to show that the Government is actively engaged on the many intricate problems involved, while Sir Stafford Cripps in the House of Commons promised legislation during the present session. Clearly we must put our own house in order before we can approach other countries.

In this connexion the report of the U.S. National Resources Planning Board on National Resources Development in 1942 should not be without interest in Great Britain. Its review of public works planning is concerned with particular programmes in the United States, but the functional development policies described in Part III of the document are of wider interest. They show how the problems of industrial location, of transport, of the utilization of special skills, of urban conservation and development, of planning for social security, and post-war planning for children and youth, are being faced in the United States.

The introduction and first part of this report, however, are of special interest as indicating the approach of the United States to these problems. The clarification of our objectives for the onward march of freedom-loving people is seen as an essential part of the war-effort. The report looks forward to securing, through planning and co-operative action, a greater freedom for the American people, and the introduction suggests that any translation of freedom into modern terms applicable to the United States must include : (1) the right to work, usefully and creatively, through the productive years ; (2) the right to fair pay, adequate to command the necessities and amenities of life in exchange for work, ideas, thrift and other socially valuable service ; (3) the right to adequate food, clothing, shelter and medical care ; (4) the right to security, with freedom from fear of old age, want, dependency, sickness, unemployment, and accident ; (5) the right to live in a system of free enterprise, free from compulsory labour, irresponsible private power, arbitrary public authority and unregulated monopolies ; (6) the right to come and go, to speak or to be silent, free from the spyings of secret political police ; (7) the right to equality before the law, with equal access to justice ; (8) the right to education for work, for citizenship, and for personal growth and happiness ; and (9) the right to rest, recreation and adventure ; the opportunity to enjoy life and to take part in an advancing civilization.

The central problem is one of freedom and the distribution of abundance, so that there may be no unemployment while there are adequate resources and men ready to work and in need of food, clothing and shelter. The obligations which go with such rights are also recognized. The preliminary objectives are visualized as planning for full employment without demanding hours in excess of forty per week or fifty weeks in the year, using to the utmost a system of modified free enterprise. The planning of demobilization and the stimulation of planning by private enterprise, including the study of the consumer market, of industrial location and of management, the relation of Government to private enterprise, schemes of public works, transport and land development, and the extension of such services as health, nutrition and medical care, all find a place in the programme, and the section on international planning indicates that American thought is well prepared for the responsibilities in European reconstruction outlined in a recent pamphlet issued by the Royal Institute of International Affairs.

That thought on reconstruction in Great Britain and in the United States should be on such similar lines is not surprising. It was an Englishman who put the case for the Colonies before his countrymen in the House of Commons better than any of their spokesmen did before the Colonists themselves. The passage of more than a century and a half has not weakened the strength of the heritage and ideals which the Anglo-Saxon democracies share. The ordeal of war has rather intensified their meaning, and Burke's words, like Jefferson's declaration, come down to us with fresh meaning and assurance of the grandeur of that common heritage. The mixing up of the two great democracies under the strain of war, the perils shared and the new comradeship in arms and in production, should assuredly lead to a fuller understanding that will promote accord and comradeship in the no less searching tasks that lie ahead in building and maintaining the peace. It is the duty of every citizen, of scientific workers no less than others, to see that every opportunity of fuller understanding is grasped and that the obstacles to co-operation, whether in peace or war, like the misunderstandings which lead to friction, are firmly and persistently swept away.

TIDES : THEORY AND PREDICTION

Admiralty Manual of Tides

By Dr. A. T. Doodson and Comdr. H. D. Warburg. Pp. xii+270. (London : H.M. Stationery Office, 1941.) 12*s.* 6*d.* net.

THE numerous and important developments in our knowledge of the tides that have been made in recent years are largely hidden away in technical journals. There has been but little written for those who wish to know something of the tides and their causes without working through the heavy mathematics which usually surrounds the subject. G. H. Darwin, in his "Tides and Kindred Phenomena", published in 1898, gave a clear non-mathematical account of the subject as it was then. Public interest in the theory of the tides was shown by the demand for further editions in Great Britain and by its translation into several foreign languages. Warburg's "Tides and Tidal Streams" (1922) was intended for seamen and for those who require a professional knowledge of the tides; but it contains a description of the chief tidal features in a form suitable for the general reader. Marmer's "The Tide" (1926) is a simple and readable account of the subject and includes references to the more recent work. In addition, many text-books of geography and allied subjects have devoted a chapter to a more or less sketchy account of the tides and their causes. But there is clearly room for a book, which, while it does not avoid mathematics altogether, yet steers a middle course between the formal treatise and the popular account for the non-scientific reader, and also incorporates the developments of the last thirty years. Such a book is the "Admiralty Manual of Tides".

The book is written with a dual purpose. It is first to give a scientific account of the tides for the use of hydrographic surveyors and naval officers, and to give it in such a form that it may be readily applied. For such, it is necessary to include some mathematics, though not more than is covered by elementary algebra and trigonometry. Secondly, for those who wish to avoid mathematics, there is a connected account, based principally upon geometrical diagrams, that is complete in itself. The mathematical paragraphs are marked with asterisks and can be skipped without vitiating the main argument. The diagrams are numerous and ingenious, and no pains have been spared to make clear the various points.

There are two main lines of investigation in tidal science. The first is practical in its outlook and intention. In it, series of observations of tidal motions are made for each port under consideration. These observations are reduced to suitable form, and from this, tide tables for the future are deduced. The most successful method of reduction is that proposed by Kelvin, the harmonic analysis of the tide into its fundamental components. Recently, this method has been much improved in form and has been extended to include shallow-water and other components which formerly impaired the accuracy of the predictions. Little theory enters into this part of the subject, except the broad principle that component periodic forces in general produce oscillations of corresponding periods in a dynamical system, though with possibly different amplitudes and phases. The method has achieved great success, as is seen in the remarkable degree of accuracy of current tide tables.

The second aspect of investigation is more ambitious and much less successful. In its ideal form it attempts, by use of the law of gravitation, and the laws of fluid motion, together with a knowledge of the contours of the ocean beds, to predict what the tides should be, without making any use of observations. In this it resembles the planetary theory of dynamical astronomy. Needless to say, the contours of the ocean beds being what they are, the problem in its general form seems impossible to solve. Some progress has, however, been made by substituting oceans of simple geometrical forms; and the tidal features of oceans bounded by vertical cliffs along meridians of longitude or parallels of latitude have been deduced. A further simplification, suitable to the cases of seas of small area, is to neglect the sphericity of the earth. Some cases of this type have been solved, giving results of great interest.

Both aspects of tidal investigation are treated in this book. The first part deals with the methods of recording the tides, and the methods old and new, non-harmonic and harmonic, of tidal prediction. While the complete processes of harmonic analysis and synthesis are necessarily used in the formation of published tide tables, it is frequently necessary to determine the high and low tides for a particular day, or the tides at various times of a day, when tide tables are not available. The authors of this book have devised a method of prediction, of the greatest simplicity and of considerable accuracy, which can be used whenever the harmonic constants M_2, S_2, K_1, O_1 appropriate to the place are available. By a judicious system of approximations based partly upon the equilibrium theory and partly upon experience, and by suitably prepared reference tables, other components than those mentioned are incorporated in the result. Arrangements are also made to include shallow-water components wherever these are significant. This method, though incorporating the mixed semi-diurnal and diurnal tides, involves very little computation. The actual work can after practice be carried through in a few minutes. Its success may be judged from the following results:

For Dover, March 25, 1936,

High water	Predicted	0h. 9m., 20·4 ft.;	12h. 28m., 20·4 ft.
	Observed	0h. 4m., 20·2 ft.;	12h. 26m., 19·8 ft.
Low water	Predicted	7h. 34m., —1·6 ft.;	19h. 53m., —1·6 ft.
	Observed	7h. 46m., —1·4 ft.;	19h. 58m., —1·4 ft.

To those who know the difficulties of the subject, these figures require no comment. The authors have given to the process the name "Admiralty Method". It was originally published in 1936, but does not seem to have received the attention it deserves.

The second part of the book deals largely with the theory of waves as applied to the tides. In this connexion the rotation of the earth is of importance, and a full account is given of Kelvin waves and combinations of them producing amphidromic systems. The application of such systems together with essential tidal observations has resulted in the successful tracing of the progress of the semi-diurnal tide in the seas about Great Britain.

The history of co-tidal maps of the British seas is interesting. The first map, due to Whewell (1836), showed a wave in the North Sea travelling down the east coast of Britain and northward up the Dutch coast. In the Flemish Bight he actually exhibited an amphidromic system, though this was not accepted as a possibility at the time. Airy in 1845 eliminated this amphidromic system and replaced it by tidal waves crossing each other in a somewhat inexplicable manner. In the English Channel, too, Airy insisted that the co-tidal lines must be curved, the speed of the waves being supposed greater in mid-channel than along the coasts, a theory that was later proved impossible. In 1904 Harris produced co-tidal maps showing an entirely different form of the co-tidal lines in the English Channel and the Irish Sea. These show degenerate amphidromic systems very close to the forms now accepted. Harris also found an amphidromic point off the south of Norway in addition to that in the Flemish Bight. Tizard's chart published in "Tides and Tidal Streams" (1909) represents an amphidromic system in the Flemish Bight, but rather remarkably makes it appear to require two tidal periods for the wave to circulate about the no-tide point instead of one! A further improvement was made by Sterneck in 1920, who got still nearer to the correct forms.

In preparing all these charts the authors mentioned above relied on coastal observations alone and ignored the extensive knowledge of the tidal streams which then existed. From 1924 onward, Proudman, Doodson and Corkan, utilizing all available observational data, and checking them against the simple formula which connects the tidal current with the surface gradient, have produced charts of the complete system of the semi-diurnal tide in the British coastal waters. This is now published as an Admiralty chart, and is probably the first of its kind to be produced in which speculation plays no part and of which all available evidence demonstrates the correctness.

The explanation of the occurrence of the three amphidromic systems which appear in the co-tidal chart of the North Sea can be made intelligible without recourse to any form of mathematics. This the series of seven diagrams in Chapter 25 does with great clearness.

A common theory found in nearly all text-books is that the principal tidal wave is generated in the Southern Ocean, that ocean, surrounding the globe, being considered the only place where the tide-producing forces can be completely effective. The tidal waves of the Atlantic Ocean, the Pacific Ocean and the Indian Ocean, are regarded as secondary waves derived from the Southern Ocean and not as waves produced by the tidal forces within these areas themselves. Against this view, almost seventy years ago, Ferrel, after a study of the Atlantic tides, decided that "if there were a dike extending from the Cape of Good Hope to the coast of South America, the tides of the North Atlantic Ocean would most probably be very nearly the same". The results of recent investigations show that the Atlantic tides, far from being secondary waves, are produced within that ocean itself, and that their magnitude is due to approximate resonance with a free period of oscillation. In a set of diagrams the authors show the co-tidal systems of the semi-diurnal tide in a series of oceans bounded by two meridians at different distances apart. These diagrams help to indicate the kind of tidal motion that may be expected in the Atlantic Ocean or the Pacific Ocean.

The double high water at Southampton, so important to the commercial prosperity of the port, has always been a matter for ingenious speculation. A favourite theory is that the phenomenon is due to the main tidal wave from the Atlantic reaching Southampton by two routes, one via the west and the other via the east of the Isle of Wight, the time difference of two hours being accounted for by the longer passage of the eastward route. Although this theory was certainly scotched by Airy a hundred years ago, and may have been exposed earlier, the idea still persists. Indeed only a few weeks ago it was broadcast by a member of the B.B.C. Brains' Trust as an established fact! The problem is fully discussed by the authors, and by simple analysis it is exhibited, as it really is, as the semi-diurnal tide modified by shallow-water tides. The point of interest which comes out, and which remains still a mystery, is why the shallow-water components should be so adjusted in magnitude and phase as to give exactly a double high water at Southampton, and yet a double low water at Portland.

The chapter on "Bores" is worked out on very simple lines. By use of Bernoulli's integral and the equation of continuity, it is possible easily to explain the main features of tidal bores and the conditions necessary for their existence.

Many other matters of interest might be commented upon, but enough has been said to indicate the scope and character of the book. It is a work which will have great value and influence in schools of navigation and geography, and will prove interesting reading for those who seek knowledge for its own sake. It removes many fallacies and misunderstandings which have persisted, and it presents the subject in a new and clearer light, at once interesting and correct.

G. R. GOLDSBROUGH.

AN INTRODUCTION TO ECONOMICS

The Social Framework

An Introduction to Economics. By Prof. J. R. Hicks. Pp. xii+212. (Oxford: Clarendon Press; London: Oxford University Press, 1942.) 7*s*. 6*d*. net.

A NEW way of handling elementary economics is badly wanted—a really new approach to the subject which will bring it into living connexion with contemporary realities. The traditional 'shape' of the subject, worked out during the second half of the eighteenth and the first half of the nineteenth century and thereafter modified only in detail, was the product of an age which had, except in the realms of foreign trade and public finance—and even there the data were scanty and often misleading—no statistical basis for study of the essential facts. This is not the sole explanation of the highly abstract and deductive methods which were employed by the classical economists; but it is a large part of the explanation. Their successors took over from them the apparatus they had devised, and have in the main continued to use it right up to the present time, partly because it had acquired a certain sanctity as the biblical justification of free trade and *laisser-faire*, and partly because it provided the readiest means of teaching economics as an academic subject, without too much soiling of the brain by contact with the sordid doings of the business world.

Gradually, this older body of economic teaching has been losing its hold. Some economists have been breaking more or less thoroughly away from it, and relying more and more on study of actual statistics rather than on abstract reasoning, while others, despising such studies except as occasional diversions from a higher task, have retired into the realm of mathematics and there built for themselves the most exquisite fairy castles of refined theory, with barely a rainbow road to connect them with the real world. Prof. Hicks himself has been a wanderer in this fairy kingdom; but now he has come back with a swift descent to the countries where things are actually bought and sold, and has presented us with an elementary text-book of economics considerably unlike other text-books and, for the beginner, very much easier to read and understand. It is true that he half promises a sequel, which will lead his readers back to the fairy kingdom, for which he has by no means lost his affection or his respect. But experience in actual teaching of elementary students seems to have taught him, as it might long ago have taught others, that the abstractions of the theory of value and of 'equilibrium economics' are not the most favourable ways of entry to the subject for the ordinary learner.

I think one reason why this lesson has not been more readily learnt by economists is that the abstract approach, deterrent as it is to the less clever students, does hold out high prizes to the clever. If a student has a high-class logical or mathematical brain, and enjoys logical or mathematical exercises, he can get a very long way very quickly in the fairyland of economic abstractions, without being in any degree held up by his ignorance of the real world; whereas, if he attempts a realistic approach, he is liable to be continually brought up against his lack of acquaintance with the facts he is trying to arrange into some sort of order. Prof. Hicks has tried to avoid this difficulty by eschewing entirely facts which have about them any taint of technique, with the consequence that his book says a lot about wages, profits, capital, shares, joint stock companies, and other things which anybody can understand, but very little about industry or production, save in the most general terms. Prof. Hicks would perhaps argue that such things belong to the realm of technique, or of applied economics, and not to the elements, with which alone he is concerned in the present volume; but I find the effect a little lop-sided. The question of monopoly, for example, is practically not dealt with at all, though it is surely vital.

All the same, I am in general very grateful to Prof. Hicks for what he has done. On the whole, I think he has rather overdone the simplicity, and sheered off certain subjects which he could have treated in a reasonably elementary way—notably money and the wide questions of the relations between the volume of employment and production on one hand and the distribution of income and the levels of consumption and investment on the other. Nor can I feel happy about a book on elementary economics from which the notion of 'margins' is practically absent; for though much evil has been done in the teaching of 'marginal' doctrines, the conception is one which has a necessary place in the study of real economic processes, even at a quite elementary level. These criticisms, however, are not meant to amount to a denial of the high value of what Prof. Hicks has achieved.

What has he done? He has produced a book which is well designed to serve two purposes—to keep his students interested, including his less clever students, and to send them on to study economics with a good idea of what it ought to be about and of the way in which statistics can be handled in the course of studying it. His book is, in the words of his sub-title, "an introduction *to* economics", rather than an elementary text-book *of* Economics—and I imagine that is what he intended it to be.

I have no space to deal with particular points, save in a sentence or two, though there are many on which I should like to comment. I do not like his unargued acceptance of economics as a 'science', or share his view of the progress which it has made. I think he treats the population problem too much in terms of mere quantity, and too little in terms of quality. I think he uses the word 'profits' ambiguously, as so many economists do. His equation of consumers or customers with employers seems to me misleading; and I think his omission of most of the problems of monopoly vitiates his treatment of the questions of capital ownership and control, which is in other respects refreshingly realistic. I could add many similar points of criticism; but, unexplained, they would serve no useful purpose, and would convey a misleadingly hostile impression of what I regard as a very useful and timely little book.

G. D. H. COLE.

A DYER IMPARTS HIS KNOWLEDGE

Dyeing with Coal-Tar Dyestuffs

The Principles Involved and the Methods Employed. By C. M. Whittaker and C. C. Wilcock. Fourth edition. Pp. vii+371+10 plates. (London: Baillière, Tindall and Cox, 1942.) 16*s*.

THE term 'chemical industries' in its wider significance comprises all those manufactures in which the formation of the products sold depends on chemical interactions and is certainly not confined to the manufacture of chemicals. All these industries, in reality based on chemicals, though still prone to pay lip service to the 'arts and practice' of their calling, are having to admit the scientific man into their management. It was Davy who wrote in 1802 that the arts of bleaching and dyeing, which the habits and fashions of society have made important, are purely chemical.

Since then a number of men with honoured names have brought chemistry into the dye house, writing books whereby their knowledge might be imparted to others. The latest of these books is from the pen of C. M. Whittaker, who for forty years has done as much as anybody both in discovery and in the application of his chemical knowledge to a very ancient art. Incisive in speech, he writes clearly and to the point, and he and Mr. C. C. Wilcock are to be congratulated on a most useful production.

This is a fourth edition; it appears only four years after the third, a fact which may be taken to mean renewed interest in dyeing under war conditions. One of the sales methods adopted by continental competitors was to give much assistance in the dye house of a customer conditional on the purchase of foreign dyes. The acceptance of this help has proved a short-sighted policy.

Dyeing in the old days used to be a question of cotton, silk and wool. Now new fibres of several kinds have arrived, which may be the forerunners of a legion, and the dyer is faced with new responsibilities. The production of Rayon yarn and staple fibre now amounts to about one sixth of that of cotton, though the increase has not been at the expense of cotton or wool. The production of silk has fallen and may well continue to do so.

Eight of the chapters deal with specific coal-tar dyestuffs, in the divisions which are customary. New sections deal with the structure and identification of textile fibres, with the preparation of textile materials for dyeing and with the principles of dyeing machinery. Some of the older sections have been re-written and all have been brought up to date, for the subject of dyeing is anything but static.

Dyeing in Great Britain has a great post-war future. There will be millions of new homes to be furnished and there is both opportunity and urge to make the textiles colourful and of good design. Let us hope the industry will be made an all-British one, free from Continental influence; with leaders such as Whittaker available there should be no difficulty.

E. F. ARMSTRONG.

WAR-TIME FARMING IN BRITAIN

Farming Handbook

By Sir E. J. Russell, Dr. H. D. Kay, Dr. W. G. Ogg, B. T. P. Barker, Malcolm Messer, Geoffrey Browne, F. H. Garner, J. A. McMillan, T. Nellist Wilks, Dr. E. Holmes, W. R. Orrell, and other Experts. Pp. iv+220+52 plates. (Norwich: Jarrold and Sons, Ltd., 1942.) 5*s*.

CONDITIONS under which farmers have to carry on their business have changed so much in the last three years that a collection of articles by well-known specialists on the most important technical aspects of agriculture is particularly welcome. The approach to the various problems of production has been influenced by the complete change in the situation in Great Britain as regards the proportion of land under the plough, the very small amount of purchased feeding stuffs available, control of the purchase and use of fertilizers, etc. An authoritative handbook of this kind helps efficient farming by presenting essential and up-to-date information drawn not only from the results of experiments and research but also from the experience of war-time farming.

The first contribution is by Sir John Russell, on crop production in war-time. This brings together the results of many experiments on different crops, and discusses a few of the more important pests and diseases of cereal crops. The article is particularly useful, written, as it is, by a scientific man with a keen sense of the significant; there is in it no material of purely academic interest. Among other contributions are articles on dairy farming in war-time, by Prof. H. D. Kay, and feeding farm livestock in war-time, by F. H. Garner, which provide the reader with the necessary information for the successful management and feeding of the dairy herd, and of farm livestock in general. The former includes a discussion on the technique of milk production, and on disease in relation to production. Other articles, also rich in practical advice, are concerned with fertilizers, fruit growing, land reclamation, farm machinery, etc.

All the contributions deserve mention, but this is impossible within the space of a short notice. Practical men, potato growers in particular, may be forgiven for starting the book by reading the contribution on potato cultivation on a large commercial scale, by G. F. Young, manager of Messrs. Smith's Potato Crisps farms; it is good, and savours of a wealth of experience gained by an observant grower.

The book is illustrated, and is well printed on good paper. It can be recommended to farmers, scientific men, and to technical and other members of War Agricultural Committees.

Torch and Crucible

The Life and Death of Antoine Lavoisier. By Sidney J. French. Pp. x+285. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1941.) 21*s.* 6*d.* net.

LAVOISIER, founder of modern chemistry, and one of France's greatest sons, has formed the subject of many biographical studies. Some of these have dealt mainly with his scientific achievements, others with his place in history. Mr. French has been very successful in his attempt to give a complete synthesis of this versatile and commanding figure in pre-Revolution France. Here we see Lavoisier not only as the inspired creator of a new chemistry, but also as one whose "active mind coordinated scientific genius, business efficiency, political vision, and public benefaction in a perfect harmony of tone". His domestic, social and political backgrounds are clearly outlined in the course of an easy, attractive—and, at times, dramatic—narrative; so are his relationships with Priestley, Cavendish (who is wrongly mentioned on p. 146 as "Lord" Henry Cavendish), and a galaxy of scientific men of his day.

The general reader should extract almost as much pleasure from this book as his scientific friends, and that is saying a great deal. Effective humanistic studies of the great figures of science are rare, and we owe a debt of gratitude to such writers as Mr. French. The appearance of this new study is a welcome herald of next year's bicentenary of Lavoisier's birth. The production of the book is sumptuous. The sole illustration is a charming reproduction on the paper jacket of David's painting of M. and Mme. Lavoisier. Unfortunately, the high price may prevent the book from attaining the wide circulation that it deserves among the lay public. J. R.

Magic and Natural Science in German Baroque Literature

A Study in the Prose Forms of the Later Seventeenth Century. By Frederick Herbert Wagman. (Columbia University Germanic Studies, No. 13.) Pp. vii+178. (New York: Columbia University Press; London: Oxford University Press, 1942.) 15*s.* 6*d.* net.

IN this richly documented work, the author shows to what extent the German intellectual laity were influenced by contemporary scientific men, such as Galileo, Kepler, Bacon, Pascal and Jungius. The principal lay writers considered are Daniel Casper von Lohenstein, Georg Philipp Harsdörfer, the author of forty volumes of poetry and prose, Eberhard Werner Happel, the author of twenty "gallant" novels and a five-volume work on the wonders of the world, Erasmus Francisci, the compiler of compendia of curiosities, Christian Weise, an opponent of the scholasticism of German universities, Johann Riemer, Johann Beer, the author of eighteen novels and one of the most gifted writers of the seventeenth century, and Johann Christoph Grimmelshausen, the author of "Simplicissimus" and representative of Christian asceticism. The influence of the scientific writers of the age appears to have had various effects. In the first place there was a waning of medieval belief in miraculous intervention in Nature and the theological interpretation of phenomena, although remnants of occult lore were still present. Secondly, a dominant rationalistic tendency was shown by the belief that Nature is autonomous in its control over mundane and sidereal phenomena and free from intervention by either divine or diabolic agency.

Ethnographic Bibliography of North America

By George Peter Murdock. (Yale Anthropological Studies, Vol. 1.) Pp. xvi+168. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1941.) 12*s.* net.

THIS first number of a new series of anthropological studies sets a high standard for its successors. The author of the bibliography has been engaged in its compilation on and off for about twelve years and the result is comprehensive and most useful, covering as it does the aboriginal population of the whole of North America. The principle of classification by tribal groups was adopted, the norm being the "nationally self-conscious tribes of regions with some measure of political development, e.g., those of the Plains". Where this standard could not be obtained a number of tribelets or local groups on approximately the same linguistic or cultural plane were united under the name of one of them.

The difficulty of charting these divisions on a map was increased by the shifting of the tribes during three centuries, which necessitated a number of compromises. The boundaries shown are approximately those of the various groups at their first extensive contacts with Europeans, and thus they are not all valid at any single period, but represent a shifting date line.

The work is organized by areas, each containing general references followed by areal références to the tribes in alphabetical order, and comprising works on physical anthropology, linguistics and archæology, as well as the more general ethnological works. The whole contains an astonishing bulk of literature dealing exhaustively with the anthropology of the whole sub-continent. K. RISHBETH.

The Furtherance of Medical Research

By Dr. Alan Gregg. (The Terry Lectures.) Pp. x+129. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1941.) 12*s.* net.

DR. ALAN GREGG, the distinguished director for medical sciences of the Rockefeller Foundation, has presented us with a thoughtful and stimulating work in the form of three lectures devoted respectively to a description of medical research, universities and foundations in relation to such research, and the medical research worker. In the first lecture he points out that research in any field comprises a series of activities consisting in selecting, observing, recording, comparing, analysing and classifying phenomena and finally drawing suitable conclusions, each of which contributes to, but cannot be substituted for, the whole process. In the second lecture Dr. Gregg maintains that, compared with a Government's subsidizing of research, foundations can much more easily work outside national boundaries and support the demonstration of theories which are not sufficiently widely accepted to qualify for Government support. Moreover, foundations can pay larger salaries than a Government is capable of doing. The third lecture contains a sympathetic account of the uphill struggle of the young research worker.

There are two appendixes consisting respectively of an outline docket film and an outline for presenting a proposal for a capital grant for building an institute.

INTERNATIONAL SYSTEMS AND STANDARDS*

By SIR RICHARD GREGORY, Bt., F.R.S.

THE Great Exhibition of 1851, in Hyde Park, London, was the pioneer of international exhibitions, and it demonstrated the industrial resources of the nations which took part in it as well as the extent of world markets in them. The International Exhibition held in London eleven years later led to the formation of the International Working Men's Association, now known as "The International", at a great public meeting in 1864 of artisans from many countries, and thus brought conditions of labour into the economic field. In the following year an International Telegraph Convention was held to regularize systems of transmitting telegraphic signals, and in 1874 the General Postal Union was formed. These were the beginnings of international trade associations, unions and relationships. The Postal Union is the best example of organization of systems and standards on an international basis. For its service the world is the unit and there are no separate territories or boundaries.

It is necessary for manufacturers to adopt and maintain standards of measurement for their products, whether for domestic or for foreign trade. Standardization within and between industries leads to better understanding and co-operation in the common interests of the producer and the consumer. It is increasingly important for the maintenance and development of foreign trade and is the best means of ensuring fairness of exchange and facilitating industrial operations. After the War of 1914–18, one of the outstanding developments in the chief industrial countries, and perhaps more particularly in Great Britain and the United States, was that of co-operation in standardization of products of allied or related industries on a national scale.

So far back as the beginning of this century, a small group representing civil, mechanical and electrical engineering was set up in Great Britain as the British Engineering Standards Association, which was incorporated by Royal Charter in 1929 and is now the British Standards Institution. There are two kinds of standardization—one concerned with fundamental standards and units of measurement, and the other with the rather wider field of industrial simplification and uniformity. The latter involves the adoption of standard specifications of material and method in all branches of industry where they can be usefully applied ; and they are constantly being added to and revised to meet new industrial needs.

For inter-Imperial trade it is desirable to have common agreement upon standards of measurement based upon the British system of weights and measures. The British Standards Institution exists to ensure this uniformity of principles and practice of standardizing bodies in all parts of the Empire. It has also the duty of converting British standard specifications into those of other countries having standardized systems, in order to facilitate foreign trade. As, however, the tendency for many years has been towards the adoption of the metric system in new industries, and this system is already used in most countries of the world, there is every reason to believe that it will become truly international in its service and that national and Imperial standards will have to be adapted to it for purposes of world trade. In recent years the scope of the work of the Institution has been very greatly enlarged, and at the present time it covers much work on rationalization and simplification, with special reference to war-time needs in relation to materials in short supply and the use of substitutes.

The use of scientific principles as the basis of measurement came under consideration in the early days of electrical engineering. A century ago there was no settled system for the measurement and statement of electrical quantities, and all electrical measurements were merely comparisons between magnitudes of the same kind. The resistance of one conductor could be compared with that of a particular piece of wire and the electromotive force of one battery could be compared with that of another, but there were no recognized relationships between these quantities or fundamental standards to represent them. The German physicist, W. E. Weber, conceived the idea of expressing the value of any electrical quantity without reference to any quantity of the same kind, and in terms not involving any physical constants except the units of length, mass and time.

The British Association took up the subject in 1861 at the suggestion of Lord Kelvin, and the result of reports of its committee was the establishment of the coherent system now adopted everywhere in science and engineering. After much discussion and correspondence, it was decided to adopt the centimetre, the gram and the second as the primary units of length, mass and time to which the various quantities used in electrical measurements could be referred. This is the C.G.S. system, and all values of electrical quantities are expressed in these units. For practical purposes, standards of electrical resistance, current, electromotive force and power have been adopted by international conferences as particular magnitudes of the centimetre, gram and second. Germany, France, Italy and Great Britain are respectively represented in the names of these fundamental electrical units by ohm, ampere, volt (Volta) and watt.

Several years ago, Prof. G. Giorgi, of the University of Palermo, proposed a new system of electrical units based upon the metre, kilogram and second (the M.K.S. system), and the International Electrotechnical Commission recommended in 1938 that this system should be adopted in all countries. The system is in no way antagonistic to the C.G.S. system, and for instructional and practical purposes it has decided advantages in simplifying relationships between fundamental electrical, mechanical and magnetic units.

In science, and to an increasing extent in engineering, measurements are usually expressed in the international units of length, mass and time. For each of these fundamental quantities it is necessary to have a primary standard of reference. The primary standards of length and mass are kept at the International Bureau of Weights and Measures at Sèvres, near Paris. They are the International Prototype Metre and the International Prototype Kilogramme. The centimetre is 1/100 of the standard metre, and the gram 1/1000 of the standard kilogram. The standard international unit of time is one second, or the 86,400th part of the mean solar day.

With the introduction of railway systems, a standard time had to be adopted for the time-tables of trains. In Great Britain the standard time adopted was that of Greenwich; in the United States, where local times differ by several hours from one another, it was impracticable to use a single time standard for the whole country. The running of long-distance trains in times which differed greatly in different States was so confusing that a remedy had to be found; and it was produced by a Scots Canadian, Sir Sandford Fleming, in 1878. His proposal was to legalize a universal day, beginning at mean noon of Greenwich time, the hours being counted 0 hour to 24 hours. A few years later a conference held at Washington approved the adoption of a single prime meridian, and also Sir Sandford Fleming's principle of dividing the whole earth into twenty-four time zones, each separated from the next by one hour. This zone system of daily time reckoning on a uniform and universal plan has become truly international and has superseded by fixed standards the medley of prime meridians and local times which kept peoples apart and hindered the development of their common interests.

---

* From an address to the Association of Special Libraries and Information Bureaux, delivered on November 7.

The division of the whole interval of day and night into twenty-four parts or hours, each of which was subdivided into parts like minutes and seconds, goes back to Babylonian times six thousand or so years ago. (The division of the angles in a circle into 60 by 60 or 360 degrees has the same origin.) The day and the night were each given a duration of twelve hours, but the lengths of the hours differed locally and with the seasons. With the introduction of clocks, it became necessary to establish a standard time interval independent of the varying lengths of the local day from one solar noon to the next. The average interval between successive noons became this standard as the mean solar day, which is the common day of civil life, and gives rise to mean solar time, or mean time. From about the end of the eighteenth century, mean time has been used in most countries instead of local solar time.

The standard time of a country or region is reckoned from a particular meridian, as it would be confusing to use a number of mean local times. Since the adoption of the zone system, standard times are referred to twenty-four meridians separated from Greenwich by a certain number of hours, with the zero hour at midnight and reckoned up to twenty-four hours, or in Great Britain up to twelve hours ante-meridian and twelve post-meridian. For practical purposes, the rotation of the earth upon its axis is invariable, and so is that of the second, or 1/86,400 part of a day, derived indirectly from it. The unit measure of time is, therefore, the same in all countries.

Various standards of measurement of length and mass (or weight) are in everyday use in different parts of the world and they impede foreign trade ransactions because of their number and compliation. In 1875, an International Conference on Weights and Measures fixed the standards of the International Metric System, and the International Bureau t Sèvres was afterwards established to preserve them. All scientific measurements are expressed in terms of the metric system, and in most countries the use of this system of weights and measures has been adopted. It was legalized in Great Britain in 1897, ut was not made compulsory, though many Chambers f Commerce and other organizations have often urged its adoption, and the Decimal Association has persistently carried on a campaign in favour of it. Developments of mechanical engineering have, however, made a large general public familiar with a number of metric measures. Radio wave-lengths are xpressed in metres, motor-car and aeroplane parts in millimetres or other subdivisions of the metre, and bores of guns and similar ordnance dimensions in the same decimalized units.

The metric system of weights and measures is truly the only system which can claim to be international in its scope and standards; and its use is likely to be extended after the present War. It does not matter much what standards or values are used for special trade or commercial transactions within customary regions or countries, but for business outside such areas, or with other peoples, fixed mercantile standards of an international kind are essential, and those of the metric system have been proved by adoption in most countries of the world to provide what is needed for international business.

In establishing the metric system on the Arabic scale of numerical notation and extending it to decimal fractions, French men of science at the close of the eighteenth century used the best methods of easy reckoning known in the history of mathematics. Their system also provided for a simple and uniform scale of relationships between the multiples and submultiples of the standard instead of the varying and unrelated quantities preserved in such tables as those of British weights and measures, upon which so much time has to be wasted in school and in everyday calculations.

By adopting the decimal scale of notation in the metric system the founders of the system used a natural plan of counting based upon the ten fingers of human hands and customary among more peoples than any other scale. A duodecimal scale has certain advantages over a decimal scale, as it permits simpler expression of halves, thirds and quarters, but it is futile to suggest the general adoption of a twelve or dozen scale either for national or international use. Whatever system of reckoning is used to express numbers and fractions, quantities will continue to be divided into halves, quarters and so on in everyday speech and practice, and new standards of weights and measures will be thought of in old denominations both locally and nationally.

As science is an international study, there must be common standards and units of measurement in all its branches in order to ensure uniform systems of comparison of results. After the discovery of radium and other radioactive elements, it became necessary to give quantitative values to their properties and to express them in agreed units. This was done by an International Radium Standards Commission, which adopted the quantity of radium emanation (radon) in equilibrium with one gram of radium as the standard unit and gave the name Curie to it. Units of physical science have thus entered the field of radioactive therapy.

One of the many useful services rendered by the Health Organization of the League of Nations has been the establishment and supply, on an international basis, of a series of 'standards of reference' by means of which the potency of many important specific agents used in medicine can be accurately determined and expressed in a commonly accepted system of notation. The series comprises standards for the assay of the antitoxins, the arsphenamines, the vitamins, insulin, the active principle of the posterior lobe of the pituitary body, many of the newly introduced sex hormones and the heart drugs.

Before the War, the international biological standards for the arsphenamines, vitamins, hormones and heart drugs were maintained at the National Institute for Medical Research, Hampstead, London, and those for the antitoxins and tuberculin at the State Serum Institute, Copenhagen. After the occupation of Denmark, the League of Nations asked the Medical Research Council to undertake the supply of the standards for the antitoxins and tuberculin to those countries which had hitherto received these essential materials from Copenhagen. More recently, an international standard for vitamin E has been established and made available, and the work towards the establishment of a standard for the important anticoagulent, heparin, has been completed.

A World Language

Primitive man was able to represent objects and motions by drawings, and by doing so he used a sign language understood by all peoples. Sir Richard Paget, who has devoted much attention to this subject, has shown that the close relationship between the movements of the hand and mouth would associate the symbolizing of objects with sounds and gestures, and thus combine art and emotional expression in a sign language. The representation of objects is still preserved in the Chinese writing of a few characters, and in the infancy of the language two or more characters were combined to suggest a third thing or idea. The Chinese language was afterwards built up of characters representing sounds or phonograms instead of pictorial symbols or ideographs. An educated Chinese to-day will, however, draw ideographs to be read by a fellow countryman who speaks a different dialect.

Drawings provide a universal means of representing objects, and their characters also convey individual or composite emotions and meanings. Many early forms of writing are conventional characters developed from pictographs of this kind, and out of these conventionalized marks alphabets were constructed or characters were combined to represent syllables. All human beings express certain emotions, such as anger and fear, by much the same sounds, signs and gestures, and all can interpret simple picture writing, as all can understand the meaning of actions reproduced in moving pictures, silent or sound. There are, however, many conventionalized forms of characters to represent these sounds and thoughts by written or printed words, and these combinations make up the many languages of the world.

Among the important problems of an international kind to be promoted now and after the War is that of a means of expression in a language easily learnt and used by all civilized peoples of the world. The International Morse Code of signals is an example of an accepted system of alphabetical and numerical communication, and what is wanted, now is an auxiliary vehicle of language which will be as widely understood. The subject of an international auxiliary language has long been under discussion, but we seem to be no nearer agreement as to what this language should be than we were after the War of 1914–18. In 1921, the British Association published a careful and comprehensive report on this subject, prepared by a committee representing humanistic as well as scientific interests, and in collaboration with the chief associations concerned with classical and modern languages as well as by consultation with a number of learned societies.

The British Association Committee was appointed after the International Research Council, at a meeting in Brussels in 1919, had taken up the question of an international auxiliary language and recommended the formation of an international committee to inquire into the position and outlook of the subject. It was hoped that a central international organization would be formed, under the League of Nations, and be empowered to make the final selection of the international auxiliary language, if feasible, and to take measures to ensure for it the greatest possible degree of stability. Chairmen were appointed to represent national committees for France, Italy, Japan and Belgium, and the chairman of the British Association Committee undertook to represent Great Britain on the Committee of the International Research Council.

The desirability of an international auxiliary language having been unanimously approved by the British Association Committee, attention was given to the advantages and disadvantages of the following three types: (1) a dead language, for example, Latin; (2) a national language, for example, English; (3) an invented or artificial language, for example, Esperanto or Ido.

The claims for the use of each of these languages as an international auxiliary language were justly and concisely stated by their own specialists in the report of the Committee. After careful consideration of this and other evidence from high authorities at home and abroad, the Committee found itself unable to pronounce judgment in favour of a particular auxiliary language for international use. The conclusions reached may be expressed as follows: (1) Latin is too difficult to serve as an international auxiliary language, and its advantages are outweighed by its disadvantages. (2) The great international languages of the past have all borne the marks of imperia prestige which prevented them from being welcomed by alien races. The adoption of any modern nationa language by the common consent of the chief nations is therefore unlikely, as it would confer undue advantages and excite jealousy, however impartial the promoters of the language might be. (3) Invented languages constructed on scientific principles and adaptable to many diverse requirements are practicable means of international communication. They are neutral and have advantages of simplicity not possessed by most national languages. Wha auxiliary language of this kind will meet with genera approval remains to be decided by internationa agreement.

In the interest of international communication and the free expression of ideas, it is to be hoped tha academic as well as scientific and commercial organizations will assist in the movement towards an agreed auxiliary language. A committee of th British Association on post-war university educatio has dealt with the subject recently in one of th sections of its report. It recommends that apar altogether from the academic study of language and literature, every university should require its student to be able to make themselves understood, by speec and writing, in an auxiliary international language The Committee suggests that the Universities Burea of the British Empire, in consultation with the American Universities Bureau and the Associatio of University Professors and Lecturers of Allie Countries in Great Britain, could take up the subjec very appropriately and prepare a report upon it. There is no better way of promoting interrelationships between the peoples of the world than that a simple common language; and the constructio of such an instrument should not be beyond the powers of responsible authorities—literary, scientifi and commercial—working together in a commo and needful purpose.

THE MENDELÉEFF–BRAUNER TRADITION IN CZECH CHEMISTRY

By Dr. GERALD DRUCE

Ever since the founding of the University of Prague in 1348, the Czechs have made their contributions to the advancement of science. In the Middle Ages, Prague and other Czech towns were centres for the practice of alchemy and a number of their pharmacies date back to these times.

Even during the dark days of the seventeenth century some Czech exiles, notably J. A. Komenský (Comenius), whose pansophism influenced some of the early members of the Royal Society, and the alchemist, Daniel Stolczius, maintained a high standard of knowledge and tried to lay the foundations for a wider and more general study of science when better days returned. Meanwhile, science was at a standstill in their homeland; no lectures or training were given until the end of the eighteenth century, when a scientific revival set in, and the biological sciences attracted most attention. Indeed, it was not until the time of Bohuslav Brauner (1855–1935) that Czech chemistry attained a world-wide significance.

Curiously enough, it was Brauner who did much to popularize the Periodic System postulated by D. I. Mendeléeff in 1869[1] and which might easily have received the ridicule accorded Newlands' Law of Octaves in 1863, though it was more likely to escape attention altogether on account of its appearing in an obscure Russian publication, especially as contemporary Western science was indifferent to so-called 'speculatory' articles.

The rapid verification of Mendeléeff's bold prediction of the existence of undiscovered elements, for which he left spaces in his Table, directed attention to his work, and it remained for Brauner and others to attempt to clear up the obscurities and anomalies. Thus, in order to establish his system, Mendeléeff had been obliged to alter certain accepted atomic weights (for example, that of beryllium) and to invert the order of others (for example, the pairs cobalt–nickel and tellurium–iodine). There were other problems such as that of the rare earths. To all these, Brauner gave his attention, as Mendeléeff frequently acknowledged[2], and there thus developed a cultural 'neo-Slavism' as distinct from the political 'Pan-Slavism' of last century. This found expression, too, in Brauner's advocacy of the Czech transcription for Russian names[3], Mendeléeff being rendered Mendělěěv, a system that is more accurate but less acceptable in Great Britain on account of the diacritical marks involved.

In 1877, Brauner adduced evidence[4] that beryllium must have an atomic weight of 9, not 13·5 as previously supposed. This was confirmed by Nilson and Petterson, so that beryllium heads Group 2 of the Table, in accordance with Mendeléeff's arrangement. From his own investigations and by a critical study of those of Crookes and others, Brauner came to the conclusion that the rare earth elements, from lanthanum to lutecium, should be lumped together in the Periodic Table[5]. This work included his classical fractional separation of didymium into the three elements, neodymium, praseodymium and samarium. Brauner next devoted himself to the task of the exact determination of atomic weights, and his figures for a number of these (cerium, beryllium, praseodymium, tellurium, thorium and lanthanum) were accepted as the standard ones[6]. He was unable, however, to clear up the problem of the inverted order of tellurium and iodine, a question that was only solved after the discovery of atomic numbers.

In 1902, when the Periodic Classification was firmly established, Brauner again visited Mendeléeff, and his lecture at St. Petersburg (Leningrad) was one of the last meetings that Mendeléeff attended. In the following year the new Chemical Institute of the Charles University of Prague was opened, largely as a result of Brauner's efforts and through the international reputation he had by then acquired[7]. With better facilities at his disposal Brauner was able to educate a generation of Czech chemists before the War of 1914–18 brought liberation to his nation. A number of these continued in his researches on the rare earths, the most noteworthy being Prof. J. S. Štěrba-Böhm, who prepared and examined the lesser known compounds of cerium, scandium and germanium. Among the substances he prepared were a long list of double cerium oxalates[8] and many double salts of scandium, while his later researches on germanium[9], starting with a supply of argyrodite, brought the early work of Winkler up to date. His son, Dr. J. P. Štěrba-Böhm, was just beginning his career and had completed an interesting research on the sulphates, selenates and carbonates of scandium[10] when the Germans marched into Prague.

Brauner's atomic weight determinations were continued at his institute by Prof. H. Křepelka, who has shown equal skill and patience in estimations relating to arsenic, aluminium[11] and silver[12], Prof. O. Tomiček, who succeeded Prof. Štěrba-Böhm, had already specialized in improved methods of potentiometric analysis which were applied to the estimation of traces of elements as impurities and in evaluating the saline contents of thermal waters[13].

Probably the most outstanding contribution to chemical science made by Brauner's successors is the polarographic work of Heyrovsky[14] and his collaborators. This method, using the dropping mercury cathode, was first described in 1925, and though a steady stream of communications on the subject continued to appear, it was not until several years after that the full significance and importance of the method were appreciated. During the last few years it has found very wide application in many different directions. With the polarographic apparatus analyses can be carried out with so little as 2 c.c. of solution of 10^{-6} molar concentration and only requires that a known amount of the material under examination be brought into convenient solution, with perhaps the elimination of any interfering element. The automatically recorded polarogram constitutes a permanent record of the information obtained.

It was used, among other things, for the detection of Mendeléeff's dvi-manganese (rhenium) in crude manganese salts[15] and may thus be said to have assisted in filling one of the gaps in the Periodic Table, allowed for by Mendeléeff in 1869. Most of these gaps have now been filled, several during the period that Czechoslovakia was able to expand its scientific and research programmes. Thus, in 1922, hafnium was discovered[16] (or re-discovered), and Brauner put in a plea for the retention of Urbain's name, celtium, for this element[17]. Mention has been made of Czech contributions to the discovery of the congeners of manganese, now known as masurium and rhenium. A third congener, which would have an atomic number of 93 and would thus be the next element beyond uranium, was announced by Koblic in 1935[18]. It was said to be present in certain residues from the working up of pitchblende for radium at Jáchymov (St. Joachimsthal), but as spectroscopic examination failed to reveal any new body, Koblic soon withdrew his claim to the discovery of bohemium, as he called the new element. In passing, it may be mentioned that in 1934 the hundredth gram of radium was extracted at Jáchymov, though by that time the Czech source of radium and pitchblende had lost its importance since far greater supplies are available in the Belgian Congo and near the Great Bear Lake in Canada. Nevertheless, Czech chemists and radiologists made valuable studies and applications of their supplies, particularly in medicine.

Brauner's life and work were influenced not only by his contacts with Mendeléeff but also by his connexions with Great Britain. His first interest in England began when as a boy he received a chemical set known as "Tutton's Chemical Box", which Prof. Frič took back to Prague from London. Later, in the 'eighties, he studied at Manchester under Roscoe and afterwards revisited England, taking the opportunity to read some papers before the Chemical Society[19]. It therefore became a part of his tradition that promising students were sent abroad to widen their outlook. Thus Štěrba-Böhm went to Paris to work under Moissan and Becquerel, Heyrovský came to London to hear Ramsay, Donnan and many other contemporary great chemists, Křepelka went to the United States to work under Richards. Between 1918 and 1938 a number of Czech students went abroad to spend at least a year of their academic life under Western influence. To-day it is only abroad that they are able to continue their researches and studies, for in the "protectorate" all universities and institutes are closed. When the nation is again liberated and the universities are opened once more, there is no doubt that the Mendeléeff-Brauner tradition of Czech chemistry will again inspire the nation's chemists to achieve results for the general advancement of science and the welfare of mankind.

---

[1] In March 1869, Mendeléeff circulated a memoir among members of the Russian Chemical Society. It set out his views on the periodicity of the elements and contained his first Periodic Table. The memoir was later reprinted in the Society's *Journal*.

LANDSCAPE IMPRESSION AND THE EXTERNAL BASIS OF NATURAL BEAUTY

By L. C. W. BONACINA

It is often said with some truth that this century has seen a welcome change from the last towards a desire to bring scientific knowledge and æsthetic appreciation of Nature more into line in human thought. Yet there were already signs of a change of outlook during the nineteenth century. That shrewd cosmopolitan thinker, Alexander von Humboldt, who helped to lay the foundations of so many of the geophysical and geographical sciences and saw so much of Nature in many lands, considered that it was not altogether possible to dissociate æsthetics from science in the study and contemplation of landscapes. As to Victorian England, it is instructive in this regard to note the respective attitudes of Tyndall and Geikie, for example, in science, and of Ruskin and Wordsworth in art and poetry.

Whatever may have been John Tyndall's theological views there can be no question that the whole outlook upon Nature of this celebrated physicist was consciously and deliberately artistic, and there are passages in his "Hours of Exercise in the Alps" which almost vie in descriptive power with Ruskin himself, leaving the reader with the conviction that to this great-hearted Irishman there was much more in the mountains than was comprised in their dimensions, form, structure and composition. Similarly, the eminent Scottish geologist, Sir Archibald Geikie, displays in his "Landscape in History and other Essays", which considers the human response to different types of country in Great Britain as also in Italy and Greece, highly imaginative insight into those imponderable but powerful environmental influences so vividly reflected in literature. Conversely, though the art critic, John Ruskin, may have given vent to irritable denunciations of scientific research, no one more loudly proclaimed the importance for creative work of careful and accurate, that is, scientific observation of natural phenomena, even going so far as to declare quite unjustly to Constable and others that no landscape painter before Turner had ever really looked at the clouds. In like manner, though William Wordsworth may have passed occasional rude remarks about geologists and astronomers, there is something in his very Nature-mysticism, unique among the great English poets, which is very reassuring from the wider philosophical and scientific point of view, and it is surely significant that a Wordsworthian text should have been selected as a motto for Nature. Throughout Wordsworth we discern in the background tacit acceptance of scientific principle which makes for stability and enhances the value of much deep and passionate expression of feeling. There is a curious passage in the second book of "The Prelude" wherein the poet is thinking of the sun and moon both as cosmical bodies and as elements in the local landscape, and says of the latter, with respect to a beloved Cumbrian vale, that she hung

> "Midway between the hills, as if she knew
> No other region, but belonged to thee,
> Yea, appertained by a peculiar right
> To thee and thy grey huts, thou one dear Vale !"

This passage is valuable as seeming to illustrate a difficult, almost painful, spiritual attempt on the poet's part to co-ordinate and harmonize astronomical knowledge with artistic perception of the moon in relation solely to the local scene. It typifies that dual attitude of mind which every contemplative lover of Nature who is both man of science and poetical impressionist will find daily opportunities to exercise.

We are now in the twentieth century in sight of a more rapid convergence of the paths followed by the scientific investigator and the interpreter of natural beauty which, it is to be hoped, will eventually unite into one clear line of approach to truth about the external world. It is highly probable that the change is being accelerated in large measure by the fact that the various theoretical enigmas and paradoxes accruing to the great modern discoveries in physics and biology, together with the perplexing far-reaching implications of the doctrine of relativity, have taken us, metaphysically speaking, out of our depth, but in so doing have served to break down the hindering rigid distinction between 'subjective' and 'objective' fact which formerly appeared final. To-day the very meaning of traditional conceptions is becoming strained and challenged to such an extent as to force thinkers into the wholesome practice of putting in inverted commas all controversial terms which it seems to them either have not been, or cannot be, exactly defined.

Hence it seems fitting at the present time to reconsider the question whether the quality of beauty cannot be brought into closer scientific relationship with the grosser attributes of natural phenomena. If those who study Nature from the æsthetic side will help men of science by paying attention to accuracy of observation and to the subjection of their flights of imagination to scientific discipline, they will find themselves automatically in scientific company without loss of any power in their own proper sphere. Reciprocally, if men of science will respond to the overtures of artists and boldly confront the question whether natural beauty with all the ennobling emotions which it begets may not be something deeper and more systematized than a wayward subjective reaction to mere matter, they may soon discover fresh vistas opening out before them, so enlarging the scope of their own endeavours. It is indeed imperative in this complicated problem that scientist and artist should work together in order constantly to put questions to one another which neither would think of in isolation.

Landscape is not, of course, the only source of the experience of natural beauty, but since it comprises so much of human environment it affords a peculiarly convenient and effective one for the interchange of ideas as between science and æsthetics. For in the landscape the observer, whether scientific or artistic, becomes aware of a multitude of sense impressions from earth, water and sky for the descriptive differentiation of which language is quite inadequate. Words fail, for example, to denote the distinctive shades of 'green' which characterize the summer foliage of various species of trees even in identical illumination. In short, landscape observation brings both the seeker of physical facts and the lover of beauty up against the subtler truths of sense impression, and this in itself is a valuable corrective of the dangerous tendency of the human mind to think in categorical or class concepts in consequence of the limitations of speech. It is seldom suspected that a large amount of unnecessary controversy in many a field of thought arises out of the fact that the names we bestow on common objects, qualities and phenomena are in essence class-concepts concealing differences between members of the same group. This is why statistics involving broad categories are inherently dangerous and require much care in their interpretation. Contrariwise, it is the peculiar value of landscape impressionistic study that it leads to the intensive exercise of every sense-faculty, and thus invites the scientific observer and the artistic observer to walk together and exchange experiences derived from the concrete presentation of particular scenes. When the senses perceive so much more of reality than words can cope with, classes and categories, which are, after all, only mental attempts to arrange Nature's bewildering medley of overlapping, interlocking facts, are soon forgotten.

The question whether beauty is a quality residing in the object perceived or in the mind of the perceiver has long been at issue in philosophical circles, but this provides yet another example of the common fallacy of expecting a simple answer to an intricate question. It is very doubtful, indeed, whether the metaphysical distinction between beauty as a 'tertiary' attribute of matter, colour as a 'secondary' attribute and shape as a 'primary' attribute will bear searching logical analysis, for obviously beauty has certain objective or external foundations whatever purely subjective or personal elements may enter into its evaluation. The external physical basis of beautiful scenery consists in the association of a vast number of elements of form, colour, lighting, movement and the like, an association in which the human spirit discerns harmonious relationship. Now it is admitted that without sentient creatures all the wealth of landscape expressed in light, colour, sound and scent would vanish from the world even though the physical counterparts thereof as electromagnetic vibrations, air-waves and corpuscular emissions would remain. Similarly, though beauty as such might cease to exist upon the earth in the absence of man with his higher spiritual faculties, the physical counterpart thereof, namely, certain pictorial relationships of material elements, would be there just the same, for the external basis of a beautiful view does not depend on the presence of a spectator. It has been argued against the reality of any objectivity in natural beauty that people appreciate it so differently, some being largely blind and insensible thereto; but it might as well be argued against the reality of the grosser attributes of matter that some persons, through physical blindness or deafness, cannot see or hear them. Certainly in the exercise of a spiritual faculty like the æsthetic sense there should be scope for beauty to be variously interpreted, since different minds will tend to capture different aspects of the truth; but within such diversity there is a large measure of unity, particularly among persons of culture. When a common standard of reference for æsthetic values has been discovered, defined and agreed upon, the fallaciousness of this kind of argument will become apparent.

As the medium through which the scenic glory alike of the heavens and the earth is witnessed by the observer, the atmosphere plays a highly critical part, because every scene must be viewed through some sort of light and weather. In fact, the diversity of scenic moods exhibited by every landscape is evidently in response to a delicate balance of meteorological factors. The fact in itself opens out a promising field for joint investigation by artists and meteorologists, as I have shown elsewhere in a series of essays on landscape meteorology. Readers of Thomas Hardy, who so skilfully portrayed his Wessex characters against what might be called the 'elemental' background of solitary heaths, woods and downs, may recall a passage in "The Return of the Native" wherein it is told that the great Dorset Heath could by its very expression anticipate the frowning of storms scarcely generated. This is more than a vivid local picture inasmuch as it typifies the mysterious manner in which the aspect of the country the world over responds to subtle unsuspected changes proceeding in the atmosphere, as though the slightest alteration in its physical condition as to light, temperature, moisture and other factors produced its counterpart in the æsthetic expressions of mountain, sea, forest, lake and the like. Theoretically it should be possible to relate the atmospheric states to the scenic expressions of the landscape, but in practice it might prove impossible to scrutinize the air with the closeness which a problem of such extreme intricacy would require. Nevertheless, the attempt would be well worth while if only it resulted in the formulation of a new vocabulary for the description of the 'scenic expression' in terms satisfactory to artists and men of science alike.

A suggestive fact in the problem of landscape beauty is the relationship between kindred features as members of a company. Just as a human personality needs to be drawn out by others, so does the scenic individuality of the trees, rocks and hills gain by interrelationship. We know how in a mountainous land the great peaks impart to one another a bearing which enhances the grandeur of the whole array, giving a new meaning to the music of torrent and cataract and the picture of gleaming glaciers. Similarly, along a high rugged coastline is it not the viewing of the multitude of rocky profiles in mutual relationship which gives the cliff scenery much of its inspiring character as we listen to the rhythmic impact of storm-waves or the low sinister murmur always uttered by the sea on such a coast in quiet weather ? Sometimes, too, the very clouds gather in noble companies, as when gloriously lit in rifted storm masses—not the less suggestive because so transient. Then take the trees. Solitary trees admittedly can be superb, as a spreading oak or beech in field or park, a commanding ash on the skyline, a graceful birch at the entrance to a Highland glen, a shapely hawthorn in full blossom on the hillside, or a rowan tossing in wind and spray amid the boulders of a moorland stream ; but it is nevertheless true that when trees of the same species grow in company with ample room for free individual development their beauty is intensified by pictorial interrelationship. Thus lofty elms often form groupings of the utmost elegance about English country lanes and village churches ; but perhaps nothing in tree-beauty can exceed the magnificence at all seasons of the year of a fraternity of great oaks disposed or inclined towards one another in every comely posture, as commonly at the foot of a range of hills. In short, the universality of this kind of scenic companionability throughout the types of Nature furnishes a fundamental fact for contemplation and will demand much thought as the foundations of beauty are sounded.

The part played by animals in scenic beauty though, perhaps, less obtrusive than that by plants, is nevertheless of great importance in introducing two distinctive æsthetic elements, the one of living forms in motion against the physical background, and the other of mental reactions to the environment, both of which add much to our human sense of the geographical personality of different regions. This is a strong argument, apart from other reasons, for the strict preservation of what remains of the indigenous fauna of Britain or of any other country where the fauna is threatened. The song and notes of wild birds are so essentially part of the beauty of the landscape that it becomes a question to what extent our enjoyment of them, unlike that of the more elaborate musical compositions of man, really depends on this fact. Thus a divine melody of Chopin or Schubert need lose nothing from being heard in a city slum, but it is at least arguable whether the full emotional appeal of the trills and cadences of the nightingale is not inseparable from the sight or memory of such an associated setting as a flowery woodland dell or garden shrubbery in the month of May. Again, though the plaintive cry of lapwings may not be particularly beautiful in itself, it can become decidedly inspiring when these handsome plovers are seen with cattle and horses wheeling in a half stormy light over vividly green, high-perched meadows climbing up to moorland, as typically in Devon and other western counties.

Evaluation of the objective foundations of natural beauty is, of course, affected by various personal factors as, for example, knowledge, which is often a safeguard against spurious, illusory or incomplete impressions. Thus at least an elementary knowledge of the geological structure of a locality is essential to the full measure of appreciation of the beauty of the countryside. An artist would certainly miss the whole æsthetic scheme of the Wealden landscapes of Kent, Sussex and Surrey, for example, if he did not appreciate the difference of contour line and of vegetation characteristic of the great parallel ranges of chalk, greensand and Wealden sandstone similar in altitude and regional climate. Knowledge of history and purpose may be the means of awakening a person's susceptibility to the exquisite beauty of our Gothic cathedrals, just as, on the other hand, it has been said that visitors to the Great Pyramid have turned away in disgust on being told that it was built by sweated labour—insensible to its symmetrical perfection which is there all the same. Perhaps in the end they who find it difficult to divorce moral principles from physical attributes may be right.

Finally, we come to the question of the metaphysical meaning of the external basis of beauty. We have seen that it needs mind to translate these external qualities into the actual spiritual experience of beauty, but why should they be present in Nature to be so translated at all ? Whence comes this mysterious expression of harmonious relationship between the component parts of what is called gross matter ? It is a proposition difficult to dispute that the physical universe does actually possess the power to excite æsthetic emotions, and if this be really the fact it points strongly to the position of those philosophers who hold that the background of the universe is mental and the expression of intelligent Deity. Beauty is part of the manifestation of law and order throughout Nature, and its existence implies that the various elements comprising a landscape or other medium exhibiting beauty are related to one another in a manner capable of arousing spiritual pleasure in the beholder. Now if we admit that man's æsthetic faculty may have been evolved in response to some real counterpart existing in Nature in her own right, we may find ourselves on the verge of new knowledge concerning the relation of the human soul to its physical environment; whereas, if we cling to what would seem to be the traditional view that the sense of beauty invests Nature with attributes she does not properly possess, being no more than a private personal subjective reaction to external influences, we shall never get the subject of beauty outside human psychology. The latter alternative spells sheer frustration, whereas the former at any rate looks promising. With this crucial issue the problem must be left for the present, but the article may appropriately be concluded with a quotation from the concluding chapter of the late Mr. J. W. N. Sullivan's "Bases of Modern Science": "The fact that a piece of matter has been reduced by relativity theory to a system of events, that it is no longer regarded as the enduring stuff of the world, makes the hypothesis that the 'physical' and the 'mental' are essentially similar very possible. . . . Our æsthetic and religious experiences need not lose the significance they appear to have merely because they are not taken into account in the scientific scheme. It is indeed possible that they will not always remain excluded from the scientific scheme." It is my growing belief that they will not and cannot remain so excluded.

ROLE OF HYALURONIDASE IN FERTILIZATION

By DR. D. McCLEAN
Lister Institute of Preventive Medicine, Elstree, Herts
and
DR. I. W. ROWLANDS
National Institute for Medical Research

AQUEOUS extracts of mammalian testis contain a 'spreading' factor which dramatically increases the permeability of the skin to injected fluids. This factor is associated with the germinal epithelium and can be extracted from spermatozoa[1]. Factors with similar diffusing properties have been obtained from the most diverse sources, for example, from culture-filtrates and extracts of many species of invasive bacteria[2], from snake and spider venoms[3] and from leeches[4]. Chain and Duthie[5] reported a remarkable mucolytic activity of these extracts characterized by a rapid fall in the viscosity of synovial fluid and the liberation of reducing substances. This observation has been confirmed and extended by other workers and it appears that these spreading factors are closely associated if not identical with a group of enzymes that hydrolyse the hyaluronic acid of the synovial fluid, vitreous humour, umbilical cord and skin[6], and which are therefore known as hyaluronidases.

The role of the hyaluronidase of spermatozoa in fertilization has not hitherto been explained. Experiments designed to show whether this enzyme causes an increase in the permeability of echinoderm eggs comparable with that occurring immediately after fertilization yielded negative results[7]. Recent (unpublished) observations on the activity of the enzyme on bovine cervical mucin during œstrus and in the resting phase were also negative.

The presence of a transparent, viscous fluid or gel in which the cumulus cells and corona radiata surrounding the tubal egg of the rat are embedded was described by Long[8]. The removal of this substance and the consequent disintegration of the cell mass is necessary to enable the sperm to penetrate the egg. According to Pincus and Enzmann[9] the dispersal is brought about by a heat-labile substance produced by the spermatozoa. Earlier work by Yamane[10] showed that a preparation of pancreas removes the cells surrounding the egg of the rabbit, an observation which was confirmed by Pincus and Enzmann[11], who used purified trypsin. They observed, however, that in addition to removing the cells, partial digestion of the egg occurred, and so it is highly improbable that the process of denudation of the egg in the Fallopian tube is effected by trypsin or a similar proteolytic enzyme. The facts recorded above suggested that hyaluronidase might be responsible for the phenomenon, and the following experiments were carried out.

Ovulation was produced in immature rats and the eggs removed from the Fallopian tube as previously described[12]. The action on the gel and cell masses of hyaluronidase obtained from various sources (see table below) was investigated. In addition, the supernatant fluid of a centrifuged suspension in Baker's solution[13] of rat sperms killed by heating at 50° C. for five minutes and a similar preparation of rabbit semen were tested, together with the secretions of the seminal vesicles (vesicular fluid) and prostate of adult rats. The action of some detergents such as sodium glycocholate was also recorded. The action of all these substances was observed in the following manner: 0·2 ml. of saline (0·8 per cent sodium chloride) was pipetted on to a watch-glass and an equal volume of enzyme dilution added and mixed. A cluster of 6–12 eggs was then immersed in the mixture and the rate of dispersion of the cells

THE ACTION OF HYALURONIDASE AND OTHER SUBSTANCES AND PREPARATIONS ON THE DISPERSION OF THE CUMULUS CELLS OF THE RAT OVUM.

Substance tested	Hyaluronidase		Time taken to disperse cumulus cells and corona radiata (min.)
	v.r.u./ml.	m.c.p. test	
Bovine testis hyaluronidase	0·6		165
	0·85		142

Sodium glycocholate 0·5 %		—	” ”
Baker's solution		—	” ”
Physiological salt solution		—	” ”

* Ten minutes heating at 100° C. destroyed activity as shown both by m.c.p. test and inability in a period of 3 hours to disperse the cells surrounding the egg.

observed under a binocular dissecting microscope. The action of hyaluronidase would appear to be solely one of liquefaction of the gel, which causes the cells to fall away from the ovum and collect on the bottom of the watch-glass. The end-point of the reaction was taken to be the complete denudation of the egg. Accurate timing of this point is difficult because a few cells may adhere to the eggs after the reaction is apparently complete. These cells, however, can be displaced quite easily by slight agitation of the watch-glass. The cells and the egg appeared to be unaffected by the enzyme.

The hyaluronidase titre of various samples of enzyme is recorded in viscosity-reducing-units (v.r.u.) or by their capacity to prevent the appearance of a typical mucin clot on the addition of acetic acid to a substrate consisting of albumin and hyaluronic acid (m.c.p. test).

The table shows that the rate at which the cumulus cells were dispersed is closely correlated with the concentration of hyaluronidase, obtained not only from spermatozoa and testis but also from *Streptococcus*, *Cl. welchii* and *Vibrion septique*. The activity of the enzyme derived from bacteria and from snake venom, and the close correlation with the activity of testicular hyaluronidase, is additional evidence that this is a specific effect of the enzyme, since it is unlikely that preparations from such diverse sources would all be contaminated with some other active agent.

Cell masses exposed to the action of detergents such as sodium glycocholate become almost invisible but the gel is not liquified. The impaired optical definition of the cells might be due to lowering of surface tension of the cell boundaries. Of interest is the fact that even after careful and prolonged washing of these cell masses, the action of hyaluronidase is afterwards inhibited. Further work is being carried out in this connexion.

The absence of any action of vesicular and prostatic secretions on the gel is additional proof that the hyaluronidase content of semen is of testicular origin. Moreover, the evidence recorded above, although entirely circumstantial, suggests that the gel surrounding the eggs in the Fallopian tubes contains hyaluronic acid.

The production of such enormous numbers of sperm for the fertilization of the mammalian ovum and the fact that the reduction in the sperm count rapidly leads to sterility has always aroused interest. It is clear that the intromission of a large number of spermatozoa is required to ensure that even a single one shall enter the egg. If a large number are required in the immediate vicinity of the egg, then their purpose may well be the production of a concentration of hyaluronidase sufficient to liquify the hyaluronic acid gel and so allow penetration of the egg by the single effective sperm. The possibility should be borne in mind that a deficiency of the enzyme may cause certain types of sterility for which there has been, hitherto, no obvious explanation, and investigations on the hyaluronidase content of semen in infertility are contemplated.

We are indebted to Dr. C. Rimington for many helpful suggestions and advice, and to Dr. H. King, who supplied the rattlesnake venom.

NEWS and VIEWS

Newton Tercentenary Meetings

IT is inevitable that, as the human race grows older, jubilees and centenaries should multiply—indeed, unless due discrimination be shown, there may be a weariness in their multiplication. But, if ever there was a single outstanding name in the history of scientific achievement, that name is Isaac Newton's, and, in the noble words of his lapidary inscription in Westminster Abbey, men of science the world over will rejoice that such and so great a glory of the human race has been permitted to dwell among us for a season. The story of Newton's surpassing achievements in dynamics and optics, of his fashioning of the mathematical tools necessary to his adventures, of his excursions into theology and chemistry is a long and involved one. Myth and legend have grown around Newton's almost superhuman figure—and yet he was human enough in many aspects. No doubt many of these myths can be dispelled by the light of modern scrutiny, but in telling the tale of his immortal work, we shall be the better able to assess the greatness of Newton's influence on his contemporaries and successors.

Newton was born on Christmas Day, 1642, and the Royal Society is marking the tercentenary year by devoting its anniversary meeting on November 30 to commemorative lectures. These will be delivered during the afternoon in the lecture theatre of the Royal Institution. Prof. E. N. da C Andrade is speaking on "Newton and the Science of his Age" at 3 p.m.; and after a brief interval, at 4 p.m., Lord Rayleigh will lecture, with experiments on "Newton as an Experimenter" and Sir James Jeans on "Newton and the Science of Today". It is also hoped to arrange a small exhibition of Newton manuscripts, instruments and other relics. The Physical Society has also arranged a commemorative lecture, which will be delivered by Prof. Andrade in the lecture theatre of the Science Museum, London on December 4 at 4.30 p.m. and in the Cavendish Laboratory on December 9 at 2.30 p.m.

Josef Bohumir Mikan (1742–1814)

J. B. MIKAN, a pioneer in the revival of the study of science in Bohemia, was born two hundred years ago, on December 4, 1742, at Česká Lípa in North

Bohemia. He studied medicine at Prague under Count William Macneven, whose Irish forbears accompanied James II to the Continent in 1689 and became landowners in Bohemia. Count William was director of medical studies in the University of Prague and took a prominent part in supporting the incipient Czech cultural revival during the era of 'enlightened absolutism' under Joseph II. Through Macneven, Mikan, who had become a practitioner at the spa of Teplice, was appointed professor of botany and chemistry at the university in 1775. This post he held for thirty-seven years, lecturing and carrying out research. He re-established proper courses of instruction and made it obligatory for students to qualify in both chemistry and botany as well as in their other subjects. In order to secure proficiency Mikan established the first chemical laboratory in Prague in 1784 and also laid out a botanic garden that is still in existence. The laboratory was a primitive affair adapted from a store-house of the original Carolinum, but it enabled him and his assistants to undertake the first analyses of many Czech spa and thermal waters.

After 1792 'enlightened absolutism' gave place to the 'reactionary absolutism' that lasted until 1848 and under which science was not encouraged. Not until 1810 were more commodious laboratories put at Mikan's disposal, and such progress as he was able to make was achieved in the face of much opposition, although a few progressive nobles gave him and his students encouragement and financial aid. Mikan was thrice dean of the medical faculty (there was no science faculty until much later) and was for many years vice-director of studies. When he retired in 1811 two appointments were made. His son, Jan Kristian Mikan, who had previously acted as his assistant, became professor of botany, and J. Freysmuth was appointed lecturer in chemistry. At his time there were no contemporary scientific publications in Czech, so that Mikan's writings are all in German and his name is usually rendered J. Gottfried Mikan. His work was, nevertheless, of vital importance for the advancement of science among the Czech nation.

Finance and Social Service in Great Britain

THE recent Political and Economic Planning (P E P) broadsheet "Fair Shares for All" (No. 192) is a fitting counterpart to that issued earlier in the year under the title "Financial Mysticism" (No. 188). The latter made a useful contribution to lucid thinking about five simple questions: the financing of the War; the risk of national bankruptcy; the value of 'warship weeks'; export policy; and the repayment of the National Debt. In regard to the first of these uestions, the point is driven home that the real ost of the War is the sweat and sacrifice it imposes, part of which is borne by the present and part by the future. In regard to bankruptcy, the false analogy between State and individual spending is exposed, while the true object of 'warship weeks' of helping us to get warships without inflation is clearly indicated. Similarly, the importance of subordinating trade policies, when peace returns, to the over-riding aim of winning the peace, is demonstrated as well as the necessity of regarding the national resources as sum of man-hours instead of a sum of pounds erling, and of the imperative need for avoiding aste of men and material either by unemployment the misdirection of resources.

In the later broadsheet, a realistic analysis is given of civilian consumption and the war effort, which suggests concisely the directions in which taxation and rationing might be further extended to promote first the war effort, but simultaneously lay the foundations for social reconstruction after the War, by giving priority to the poorest groups of the population as part of a national consumption policy to wipe out malnutrition. A much more determined attack on the 'vicious spiral' from the under-consumption end is required. The essential problem here is that of subsidizing consumption among families with several children, and accordingly family endowment is now the chief weapon which must be used to combat under-consumption, though the problems of prisoners, the sick, the families of men in the Forces, and of workers receiving unusually low wages, must be considered. Much more needs to be done in respect of school-feeding services and tax relief for children before the existing services providing family endowment benefits can be regarded as adequate. Further development of the subsidized food schemes, a definite family allowance scheme, co-ordinated with existing services and for occupations where earnings are very low, and wage increases to a reasonable minimum are other proposals designed to secure a comprehensive policy and develop the maximum war effort.

Illusions about the Size of the Moon

PROF. E. G. BORING and his associates at the Harvard Psychological Laboratory have quite recently undertaken precise measurements to determine how large the moon appears, both on the horizon and near the zenith (*Sky and Telescope*, Sept.). Various observers compared the moon with an artificial moon placed at a standard distance, and the size of the artificial moon could be varied to agree with the real moon. An arrangement was made to control the orientation of the observer's head, so that the angle between direct vision and the elevation of the moon could be measured. The artificial moon, placed at a distance of 12 ft., appeared from 2° to 6° in diameter to people with normal vision and using both eyes. The experiments were conducted to choose between four modern theories which are associated with the physiology of the eye. The old theory that the moon is contrasted with terrestrial objects when near the horizon is ruled out by the fact that this illusion disappears when we view the horizon moon with the head upside down. The theory that the celestial sphere looks flattened overhead, the apparent distance of the moon thus varying, is also eliminated. Ames's theory alone out of the four modern theories is not finally rejected. When the eyes are raised, it has been found that the right eye tends to rotate clockwise, as viewed from the back, with respect to the left eye, and this fact may explain the moon illusion for binocular vision. It is admitted, however, that the results are not conclusive.

Technical Basis of Sound Reproduction

AT the November meeting of the British Institution of Radio Engineers, held at the lecture hall of the Institution of Structural Engineers on November 21, Dr. L. E. C. Hughes read a paper on "The Technical Basis of Sound Reproduction". His treatment of the subject was based on his experiences as technical adviser to the Central Council for School Broadcasting, and was general in character. Dr.

Hughes described the various degrading effects on sounds by the chamber in which they are emitted or reproduced. The final test is always a subjective one, and owing to the short memory of the ear it is necessary for comparisons between the original performance and the reproduction to be direct. This is difficult, and the method Dr. Hughes advocated was to use two separate chambers with a microphone in each to represent the listener, and to compare their outputs subjectively at the remote end of a very good quality amplifier.

Dr. Hughes explained that each letter has its own requirements in the matter of frequency range for good reproduction of speech, but he stressed the point that the final test is always an aural one in the tests conducted by the Apparatus Approval Committee of the Central Council for School Broadcasting, where non-technical audiences vote subjectively on the quality of reproduction on a scale attained entirely by experience. In the discussion which followed, doubts were expressed as to the validity of subjective tests, but Dr. Hughes stated that a completely new panel had, in duplicate tests, returned votes which were within 1–2 per cent in agreement with the regular panel.

Michelia Timbers for Aircraft

A SERIES of leaflets has recently been issued from the Forest Research Institute, Dehra Dun, on utilization matters. No. 17 deals with the species of Michelia of which the *champaca* (champ) is the most important, being fairly common in Assam and cultivated all over India for its fragrant flowers. Its true habitat is in the Eastern Himalaya, Sikkim and Assam. There are four other species of the genus in India, but they are less abundant. The timber of the five species is very similar in weight and strength and is only slightly heavier than spruce (being about 33 lb. per cubic foot as against 30 lb. for spruce) and compares very favourably with spruce in strength.

Michelia timber seasons without difficulty or degradation; it is straight grained and very easy to work both by hand and machine tools. It can, it is said, be finished to a beautiful smooth surface and is a pliant wood to handle; also it can be peeled on a rotary lathe and sliced on a slicing machine to produce excellent veneers for plywood. It is not surprising, therefore, that this timber should prove very suitable as a substitute for Sitka spruce in the manufacture of aircraft. It is stated that though supplies are limited, if the wood of these species is reserved for aircraft construction in India alone, available supplies would go some way to supplying the needs of the industry. This takes one back to a century ago when the same remarks were being made in Malabar and Tenasserim in connexion with the teak demands of the Bombay Dockyard and the Admiralty in Great Britain.

Indian Woods for Battery Separators

LEAFLET No. 14 of the Utilisation Section, Forest Research Institute, Dehra Dun, deals with investigations into woods for battery separators. The battery separator is a thin sheet made of wood, ebonite or glass interposed between the positive and negative plates of an acid storage battery in order to prevent the plates from touching each other during handling or use, while at the same time allowing the ionic exchange to take place in the electrolyte. When wood is used its essential characteristics must be good permeability, freedom from volatile acids, low percentage of tannins and resinous matter, sufficient mechanical strength and resistance to chemical action of the electrolyte. The most commonly used timber has been the American *Chamæcyparis lawsoniana* or the Port Orford cedar. The Indian Forest Research Institute has been investigating the suitability of Indian timber for the purpose for some time past. The research work has shown that the following are suitable for use as battery separators: *Adina cordifolia* (*haldu*), *Cupressus torulosa* (cypress), *Michelia champaca* (champ or champak), and *Talauma phellocarpa*. The leaflet describes some of the tests carried out. As regards the Michelia it is more likely to be earmarked for aeroplane construction than battery separators, unless the wastage from the former can be utilized for the latter.

Horticultural Science

SEVERAL papers upon scientific aspects of gardening have appeared in recent numbers of the *Journal of the Royal Horticultural Society* (vol. 67). Dr. B. A. Keen expounds his doubts of the value of hoeing except for the destruction of weeds (Part 10; Oct. 1942). This conception must now express the ideas of many workers who have considered the mechanism of water movement in soil. The experiments quoted are upon an agricultural scale, but should also have direct reference to horticulture. M. Mather publishes further work upon the effect of the moon on germination and seedling growth (Part 8; Aug. 1942). He again finds no consistent lunar influence, but can explain all the differences recorded for tomato and maize by the effects of temperature and light. The moon is not known to exert a great influence upon these two factors. Other experiments on growth of tomatoes are those of Dr. M. A. H. Tincker (Part 8), who finds that extracts of the vitamins in yeast do not improve growth or enhance the vitamin B_1 content of the plant.

Air Vice-Marshal A. E. Borton records (Part 10) satisfactory control of the Rhododendron bug *Stephanitis rhododendri* by spraying with an atomized pyrethrum wash. 'Die-back' disease of apricots makes cultivation of this crop difficult in Great Britain. H. Denham and H. Wormald show (Part 8) that the trouble is caused by the brown rot fungus *Monilia cinerea* (*Sclerotinia laxa*). It can be controlled by the removal of shoots with wilted flowers or leaves, or dead twigs. Spraying with copper carbonate washes is also mentioned.

Rubber Economy in Typewriter Cylinders

ACCORDING to an article by A. R. Kemp (*Bell Lab Rec.*, 20, No. 12; August 1942) savings in the rubber used for typewriter cylinders are now possible as a result of experiments recently carried on in the Bell System Chemical Laboratories. These cylinders consist of an arbor of steel or wood over which is slipped a sleeve of rubber. The rubber is vulcanized on the arbor, and then ground to the proper size and to roughen its surface so as to grip the paper firmly. With extensive use, the cylinders become hard and glazed, and no longer hold the paper securely. They have then been returned to the factory to have the old rubber removed and new rubber put in its place. It has been estimated that from fifty to one hundred thousand cylinders need to be renewed each month.

Tests have shown that by sand-blasting the glazed cylinders for two or three minutes, using No. 90 steel grit and an air pressure of 15–20 lb., a surface was formed that in many ways was superior to the original. The reduction in cylinder diameter due to this resurfacing is less than 0·002 in. Cylinders treated in this manner have had hard service in Bell Laboratories for more than six months without showing need for further treatment. Cylinders that have been ground have a grooved structure, while sand-blasted cylinders have an irregular pattern of minute projections that grips the paper firmly in all directions. The sand-blasting, moreover, knocks out the fine particles of filler compound that otherwise would reduce the friction between paper and cylinder, much as talcum powder would. Typewriter cylinders vary considerably in size, but on the ordinary letter-page machine the rubber weighs about 1 lb., and with more than a million replacements a year, sand-blasting promises a considerable saving of rubber compound.

Cancer Mortality

THE June issue of the *Statistical Bulletin*, the organ of the Metropolitan Life Insurance Company of New York, contains an editorial based on a series of observations extending over a number of decades, from which the following conclusions emerge. While the recorded mortality among males from all forms of cancer has shown an increase by about one third in the course of thirty years, the rate among females has changed but little. Towards the end of the period there has been some improvement among females, while there has been a slackening in the upward trend for males. The result has been that the rates for males and females at ages 1–74 which widely differed in 1911–15 have converged to a common level of 86·8 per 100,000 in the quinquennium 1936–40. A substantial cause of the rise in cancer mortality among males is probably due to improved diagnosis—a supposition confirmed by a consideration of the mortality from cancer of the various organs. Since 1911 mortality of cancer of the peritoneum, intestines and rectum has practically doubled in the case of males and increased by about 50 per cent in females. The mortality from cancer of the pancreas and prostate has also risen sharply. The rise in the death-rate from cancer of the lung and pleura has been attributed to improvement in diagnostic technique. The most hopeful outlook occurs in the case of those organs which are readily accessible such as the female genital organs, the skin and mouth, in each of which the mortality has declined since 1911. Cancer of the breast is exceptional in that, in spite of its accessibility, its mortality has increased during the thirty years. The improvement due to early recognition and treatment of suspected growths is illustrated by the fact that the American College of Surgeons has records of more than 36,000 cases of so-called "cured" cancer.

Health of the United States Army

ACCORDING to the War Department, the army training in the United States is in better health than ever during war-time. It is anticipated that the general hospital admission rate in 1942 will be about 10 per cent lower than in 1941. Venereal disease is substantially less than during the War of 1914–18, the syphilis rate being the lowest in army history. The total venereal diseases rate was 40·5 per 1,000 men in 1941 and 38 per 1,000 during the first six months of 1942. Throughout 1941 and thus far in 1942, the death-rate has been the lowest in army history. During this period, from one half to two thirds of the deaths resulted from external causes such as traffic accidents. The meningitis fatality rate in the army is far below that in civil life. The malaria rate per 1,000 men in the Continental United States was only 0·61 for the first eight months of 1942 as compared with 1·24 in 1941. Universal vaccination has virtually eliminated smallpox, and rigid sanitary control and inoculation have rendered typhoid almost non-existent. The incidence of scarlet fever is now extremely low.

Public Health in Brazil

THE September issue of the *Boletín de la Oficina Sanitaria Panamericana* contains an article by Dr. João de Barros Barreto, director-general of the National Department of Health, Rio de Janeiro, who states that this department has the following sections: administrative service; divisions of public health and hospital organization; Oswaldo Cruz institute for the study of prevalent diseases and the manufacture of sera, vaccines and chaulmoogra esters; national services for leprosy, tuberculosis, yellow fever, malaria, plague, mental diseases, control of medicine, port sanitation, water and sewerage, and vital statistics, and since September 23, 1942, the national service for cancer. Courses in public health are given by the National Health Department and include microbiology, immunology and parasitology, vital statistics, physiology, urban and rural sanitation, epidemiology and prophylaxis, industrial, child and mental hygiene, nutrition and public health organization and administration. A number of scholarships are granted to medical men through the Panamerican Sanitary Office.

Fevers in the Sudan

THE recently published report, for 1940, of the Director of Medical Services of the Sudan, contains an account of an epidemic of yellow fever which broke out in that country in July and continued until the end of 1940. The number of known cases was 15,633, of which 1,627 were fatal. The real incidence was probably greater as many of the cases were mild and atypical, and therefore were not notified. The epidemic was particularly remarkable in that, so far as was known, yellow fever had never occurred previously in the Sudan or indeed in any part of the Old World east of the centre of Africa. The report also contains an account of a long-continued epidemic of relapsing fever which started in 1936 and reached its peak in 1940 with 1,487 cases. It is a remarkable fact that though relapsing fever is louse-spread, no mention is made in this report or any of its predecessors of typhus, so that this disease seems to be absent from the Sudan.

Books on Historical Medicine and Science

THE firm of Schuman's, 20 East 70th Street, New York, has recently issued a catalogue "Medical Miscellany List 'F' ", containing a number of interesting books and periodicals of which the following may be mentioned: Sir Benjamin Brodie's "Physiological Researches" (1851), Edwin Chadwick's "Report on the Sanitary Condition of the Labouring Population of Great Britain" (1843), A. Weismann's "Vorträge über Deszendenztheorie" (1904), first edition of Gray's "Anatomy" (1858), William Hamilton's "Observations on the Preparation, Utility and Administration of Digitalis Purpurea or Foxglove" (1807), Francis Home's "Medical Facts and Experiments" (1759), Hufeland's "Art of Prolonging Life" (1797), Lord Lister's "Contributions to Physiology and Pathology" (1859), Thomas Bateman's "Reports on the Diseases of London, and the State of the Weather from 1804 to 1816" (1819), Puschmann's "Handbuch der Geschichte der Medizin" (1902–1905), the first two volumes of *Archiv für Physiologie* (1796–97) and a number of runs of the *Lancet* from 1848 until 1871.

Recent Earthquakes

During the third quarter of 1942, the epicentres of ten strong earthquakes have been found chiefly from instrumental data from American observatories. The first four epicentres in July and August were determined at St. Louis by the Jesuit Seismological Association, and the others in August and September by the United States Coast and Geodetic Survey, in co-operation with the Jesuit Seismological Association and Science Service. On July 8 the epicentre was in Chile (24·5° S., 69·5° W.) with a depth of focus near 175 km. A later earthquake on July 8 and one on July 12 had their epicentres near the coast of Ecuador (0·3° S., 80·2° W.) and a depth of focus near 500 km. The latter was reported felt at Guayaquil. On August 6 the earthquake had its epicentre in the Pacific Ocean off the coast of Central America (12·9° N., 92·1° W.). On August 23 a shock had its epicentre in the Pacific Ocean between the Kamchatka Peninsula and the Aleutian Islands (51·5° N., 163° E.). Further shocks in the same region were on September 2 (52·5° N., 170° W.), September 4 (52·8° N., 169·2° W.), and September 9 (53·1° N., 165° W.). Sequences of shocks in this manner are not uncommon and the present group is somewhat to the west of a similar group some months ago. The shock of August 24 had its epicentre near the coast of Peru (14·5° S., 75·5° W.) with a depth of focus between 50 km. and 100 km. A further earthquake with its epicentre in the Pacific Ocean off Central America (12·5° N., 91° W.) occurred on September 4. On Thursday, October 29, an earthquake was felt in Western Turkey, including Istanbul and Smyrna. No damage has been reported.

A New Comet

A comet was discovered by Oterma on Sept. 11d. 23h. Its position at the time of discovery was R.A., 23h. 51m., Dec. + 6° 20′, and its magnitude was 13. A later telegram announces that the comet was observed again on Nov. 6d. 20h. 16m., and its position then was R.A., 4h. 11m., Dec. − 0° 47′. Its magnitude had not altered. It was stated to be moving slowly northward. An orbit will be computed when a third position is obtained.

The Night Sky in December

New moon occurs on December 8d. 01h. 59m. u.t., and full moon on December 22d. 15h. 03m. Conjunctions during the month are as follows: Dec. 6d. 13h., Mars in conjunction with the moon, Mars 5° S.; Dec. 20d. 17h., Saturn in conjunction with the moon, Saturn 3° N.; Dec. 24d. 13h., Jupiter in conjunction with the moon, Jupiter 3° N. Occultations of stars brighter than magnitude 6 are as follows, the times referring to Greenwich:

	d.	h.	m.		
Dec.	12	19	15·0	μ Capricorni	*D*
	15	22	13·4	14 Ceti	*D*
	20	19	32·7	α Tauri	*D*
		20	44·5	α Tauri	*R*
	26	03	06·2	o^2 Cancri	*R*
			34·0	o^1 Cancri	*R*
	27	23	32·9	45 Leonis	*R*
	28	02	50·2	ρ Leonis	*R*

Mercury, Venus and Mars are not well placed for observation during the month. Jupiter, in Gemini, souths at 2h. 10m. about the middle of the month and is well placed for observation. Saturn, in Taurus, souths at 22h. 50m. in the middle of the month and can be observed all night. The Geminid meteor shower is active during December 7–15, the radiant being close to α Geminorum. The winter solstice commences Dec. 22d. 12h.

Announcements

The Minister of Supply has appointed Prof. J. E. Lennard-Jones, Plummer professor of theoretical chemistry in the University of Cambridge, to be chief superintendent of armament research, and Mr. F. E. Smith, of Imperial Chemical Industries, Ltd., to be chief engineer and superintendent of armament design. These appointments have resulted from the recommendations of a committee under the chairmanship of Dr. H. L. Guy recently appointed by the Minister of Supply to review the machinery for the conduct of research, design, and experimental work in connexion with the development of guns, small arms, and ammunition.

Dr. C. D. Darlington, director of the John Innes Horticultural Institution, has been invited to deliver lectures to the Mendelian Society of Lund in Sweden. He will journey to Sweden under the auspices of the British Council, and, in addition to his lectures at Lund, will speak on cytology to learned societies in other centres, and will also deliver a number of general lectures on a broad biological topic.

The Earl of Moray and Mr. J. M. Bannerman have been appointed members of the Forestry Commission in succession to Sir John Sutherland, who has submitted his resignation, and to fill another existing vacancy. At the request of the Secretary of State for Scotland, Sir John Sutherland has agreed to continue to attend meetings of the Commission so that his experience may be available when matters relating to Scotland are discussed.

The council of the Royal Meteorological Society has awarded the Buchan Prize for 1943 to Dr. T. E. W. Schumann and Mr. Gordon Manley. The Prize is awarded biennially to the authors of the papers published in recent issues of the Society's *Quarterly Journal* which have been adjudged to contain the most important original contributions to meteorology.

Connexion between the Penetrating Non-ionizing Component of Cosmic Radiation and Penetrating Showers

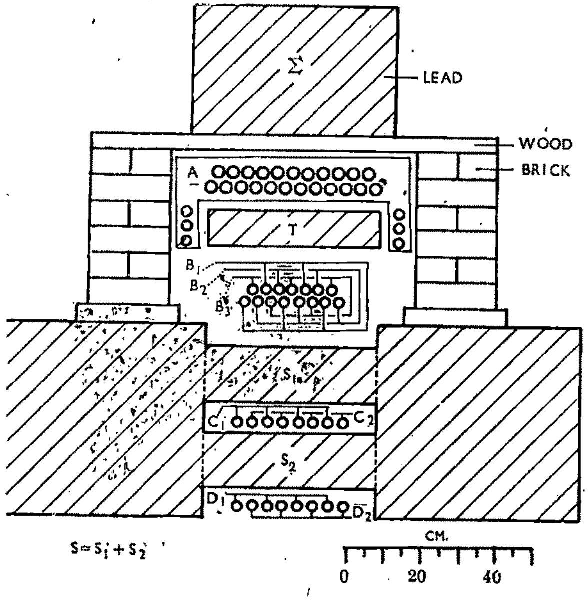
IN a recent publication[1] we suggested that there is a connexion between penetrating showers produced at sea-level and the penetrating non-ionizing radiation discovered by Rossi and Regener[2] on Mt. Evans and by us at sea-level. The present investigation was undertaken with the object of establishing such a connexion. The results show that a considerable fraction of the penetrating showers are produced by a penetrating non-ionizing radiation, but that only a small fraction of this radiation produces penetrating showers.

The experimental arrangement, illustrated diagrammatically herewith, was a combination of the arrangement by which penetrating showers were originally observed[3] and the arrangement used to observe the non-ionizing radiation[1].

Sevenfold coincidences $B_1-B_2-B_3-C_1-C_2-D_1-D_2$ involving counters out of each of the three trays, B, C and D, were recorded; one of us has shown for a similar arrangement[3] that such coincidences are mainly due to penetrating showers.

If the absorbers T and Σ were removed, only penetrating showers coming from the air were recorded. On placing an absorber T above the counter tray B, the coincidence rate increased by $0{\cdot}289 \pm 0{\cdot}062$ coincidences per hour, the increase being due to the showers produced in T. To show that a considerable fraction of these showers were due to non-ionizing agents the following method was used.

The absorber T was covered on five sides by a set of anti-coincidence counters consisting of thirty-five counters in parallel. Thus a non-ionizing particle producing a penetrating shower in T could give rise to an anti-coincidence, that is, a sevenfold coincidence not accompanied by the discharge of any of the counters A. With $T = 10$ cm. of lead, $0{\cdot}086 \pm 0{\cdot}018$ anti-coincidences per hour were recorded. All these anti-coincidences might have been due to non-ionizing particles, but to show that at least part were, in fact, due to non-ionizing rays and not to some spurious effect, observations were carried out with a variable absorber Σ placed above the anti-coincidence set. It was expected that some of the non-ionizing particles moving towards T would be absorbed in Σ. Thus the decrease of the rate of anti-coincidences with increasing thickness of Σ was a measure of the rate of anti-coincidences due to non-ionizing particles.



Absorbers		Time	Coincidences		Anti-coincidences	
T (cm. Pb)	Σ (cm. Pb)	hr.	Total No.	Rate per hr.	Total No.	Rate per hr.*
0	0	306 : 15	162	0·529 ±0·042	5	0·023 ±0·010
10	0	380 : 30	311	0·818 ±0·046	24	0·086 ±0·018
10	5	1289 : 56	1100	0·853 ±0·026	59	0·063 ±0·008
10	35	1344 : 20	924	0·688 ±0·023	33	0·033 ±0·006

* Corrected for random coincidences.

It is clear from the data given in the accompanying table that the anti-coincidence rate falls considerably as Σ is increased from 0 to 35 cm. of lead. We conclude, therefore, that some of the showers produced in T are produced by non-ionizing particles.

The non-ionizing radiation does not seem to consist of photons, as photons would be almost entirely absorbed in 5 cm. lead, while our observations show a marked absorption as Σ is increased from 5 cm. to 35 cm. of lead. It is not unreasonable to assume that this radiation is part of the penetrating non-ionizing radiation reported previously[1,2].

As the range of the non-ionizing radiation cannot be determined accurately from our data, it is difficult to estimate its rate of incidence. Rough calculations, which will be given elsewhere, indicate (1) that the rate of incidence is about 1 per cent of the rate of non-ionizing radiation observed with our previous arrangement[1], and (2) that one third of the penetrating showers produced near sea-level are produced by the penetrating non-ionizing radiation.

Purification and Chemistry of Penicillin

THE lability of penicillin is such as to preclude most of the ordinary chemical manipulations. Attempts by us to purify the material by the procedure of E. P. Abraham and E. Chain[1] had little success, perhaps for reasons which appear below. After a lengthy search, we have developed a new chromatographic technique involving a chemical reaction which for the first time provides a rapid means of concentrating penicillin to a high degree with the minimum risk of chemical change.

Penicillin is chromatographed from an organic solvent such as ether or amyl acetate on a column consisting of a water-retentive support such as silica-gel or 'Hyflo-Supercel' which is associated with an inorganic base such as a hydroxide or carbonate of an alkali or alkaline earth metal. The base is applied either in the form of a dilute solution in water, or as a mechanical mixture, or preferably precipitated on the carrier before use; a suitable column consists of a 2·5 per cent precipitate of an alkaline earth carbonate on silica-gel. Doubtless the process is a combination of 'chemical' chromatography and 'partition' chromatography, the constituents of the crude penicillin being separated primarily according to the strengths of the component acids; whereas in the adsorption column, differences in adsorption affinity are magnified by a large number of elutions and adsorptions, in the present process differences in acid strength are magnified by repeated neutralization and acidification. The process is of general applicability, and we have found it can conveniently be used to separate alkaloids on silica-gel retaining a solution of sodium hydrogen sulphate.

The above process leads to theoretical recovery of penicillin and easily affords manifold concentration. Most of the work referred to below was carried out on material (strontium salt) containing *ca.* 500 units/mgm.[2]. We have on occasion obtained material containing 750 units/mgm.

Penicillin obtained by us in the form of its strontium salt after drying *in vacuo* at 60° or 100° gives analytical figures in agreement with the formula $C_{24}H_{34}O_{11}NSr$; electrometric titration gives an equivalent of 249, the smooth curve showing only a single inflexion, from which it would appear that the two acid groups are not adjacent. The salt is yellow and possesses an absorption band at 265 mμ ($E^{1\%}_{1\text{cm.}}$ *ca.* 390) which is unaffected by treating with aluminium amalgam; it appears to have no measurable optical activity.

Very mild inactivation is accompanied by fission of the molecule. We have used dilute acid, alkali, or moist organic bases such as aniline, methylaniline, dimethylaniline or *p*-nitraniline for this purpose (fission with ammonia is more complicated and leads for the first time to fluorescent materials). The isolated products are (*a*) a substantially colourless water-soluble acid, (*b*) varying quantities of a yellow almost insoluble pigment, and (*c*) acetaldehyde which is accompanied by a minute quantity of an αβ unsaturated aldehyde, $C_7H_{12}O$, the significance of which is questionable; no carbon dioxide is liberated. The water-soluble acid affords ether-soluble and ether-insoluble acids on further hydrolysis, of which the second gives a positive ninhydrin reaction; it thus appears to be a simple peptide. The pigment, $C_{16}H_{20}O_6$ or perhaps $C_{16}H_{18}O_5.H_2O$, shows two characteristic colour reactions which we have found reliable indications of the localization of penicillin on the column: the first is a transient cherry-red colour with strong nitric acid, and the second a permanent deep red colour with a dilute solution of sulphuric acid in glacial acetic acid. The pigment possesses absorption bands at 261 and 397 mμ ($E^{1\%}_{1\text{cm.}}$ 290 and 305) but does not appear to be a quinone; although it titrates as a monobasic acid it is more probably enolic in character (a tetronic acid ?). Whenever penicillin is treated with aluminium amalgam it ceases to give the above colour reactions and an insoluble hydrolysis product, now colourless, gives analytical data corresponding to $C_{16}H_{20}O_5$, indicating that this treatment results in reduction. Ozonolysis of the pigment provides acetaldehyde together with other products as yet unidentified, while degradation with alkaline permanganate gives at least three molecules of oxalic acid.

We thank the Therapeutic Research Corporation of Great Britain, Ltd., under whose auspices this work is being done, for permission to make this preliminary statement.

Notatin: an Anti-bacterial Glucose-aerodehydrogenase from *Penicillium notatum* Westling

IT has been shown[1] that when a selected strain of *Penicillium notatum* Westling is grown on a Czapek-Dox medium an anti-bacterial substance is produced which differs in the majority of its properties from penicillin[2,3,4]. This anti-bacterial substance was originally named 'Penicillin A', but in order to avoid confusion with penicillin we now prefer the name 'notatin'. This substance is isolated by concentrating the culture filtrate to approximately one fifth of its volume under mild conditions and precipitating the concentrate with acetone or by producing a complex with tannic acid from which notatin is regenerated by extracting the tannic acid with acetone[5]. The crude substance can be purified further by regeneration from the complexes which it forms with tannic acid and with Reinecke salt. The average yield of purified notatin is 3–4 gm. from 100 litres of culture filtrate.

Notatin is a buff-coloured powder freely soluble in water, but almost insoluble in organic solvents. The aqueous solution has *p*H 6–7 and the activity is rapidly destroyed at *p*H's below 2 or above 8 or by heating to 60° C. Notatin is decomposed by 70 per cent aqueous methyl alcohol at 30° C. and by aqueous trichloracetic acid, yielding a precipitate of protein and a solution containing the prosthetic group, both of which, tested singly, have no anti-bacterial action A typical sample of notatin afforded the following figures on analysis: C, 50·0; H, 6·7; N, 11·8 P, 0·58 per cent, the results being corrected for moisture (11·1 per cent) and ash (5·3 per cent). Specimens containing less than 1·4 per cent ash have been prepared. Some preparations contain a small quantity of catalase, but only traces are present in others

Notatin affords positive reactions in many protein tests and it also responds to the luminoflavin test The absorption spectrum in aqueous solution exhibits maxima at 280, 375 and 465 mμ, which characterize it as a 'yellow enzyme'. The extinction coefficient of the absorption band at 465 mμ runs parallel with the anti-bacterial activity. The other properties of the substance are also those of a flavoprotein and by assuming the molecular weight 73,000, which is that of the majority of flavoprotein enzymes, it can be calculated from the extinction coefficient of the absorption band at 465 mμ that the purity of our best preparations is about 90 per cent. A purified solution of the non-protein part of the molecule was prepared by treating a solution of notatin with trichloracetic acid and applying Warburg and Christian's method[6]; the absorption spectrum of this solution was closely similar to that of riboflavin. The silver salt of the prosthetic group is insoluble, and notatin is therefore probably a dinucleotide.

Notatin only exerts its anti-bacterial activity under certain well-defined conditions, but under these conditions it is a very powerful bactericide. The conditions are:

(1) presence of oxygen;
(2) presence of glucose;
(3) absence of appreciable amounts of catalase.

Our best preparations completely inhibit the growth of *Staphylococcus aureus* in dilutions as great as 1 part in 1,000,000,000. They are also active in very high dilutions against other Gram-positive and Gram-negative organisms including *Strep. hæmolyticus*, *Strep. pneumoniæ*, *Bact. typhosum*, *Bact. paratyphosum A* and *B*, *Bact. typhi-murium*, *V. choleræ*, *Bact. anthracis* and *Proteus vulgaris*.

It has been found that in the presence of notatin, glucose is converted by oxygen to gluconic acid with simultaneous production of hydrogen peroxide. Quantitative experiments indicate that the oxidation may be represented by the equation

$$R.CHO + H_2O + O_2 \rightarrow R.COOH + H_2O_2,$$

although there is a deficiency of hydrogen peroxide when notatin is contaminated with catalase. The whole behaviour of notatin is thus consistent with the view that it is an enzyme similar to, but much more potent than, the glucose oxidase obtained by Müller[7] from *Aspergillus niger* mycelium and further examined by Franke and his collaborators[8], who consider it better described as a glucose aerodehydrogenase.

In vivo experiments are in progress and will be reported at a later date; there is evidence of a therapeutic effect with exceedingly minute doses of notatin.

In a recent publication[9] Kocholaty mentions 'penatin", a newly discovered anti-bacterial substance produced by *Penicillium notatum* Westling, which differs from penicillin. The chemical and bacteriological results given in his communication are insufficient to show whether penatin is identical with notatin.

The work described above was carried out under the ægis of the Therapeutic Research Corporation of Great Britain Ltd. A more detailed account of the investigation will be published in due course.

Transformation of Benzpyrene in the Living Skin of Mice into a Compound Soluble in Dilute Alkali

THE skin of white mice painted with benzpyrene fluoresces violet at first, but within two to four days the colour of the fluorescence changes slowly to blue. The blue persists for two to three weeks, until it cannot be distinguished from the natural bluish-white fluorescence of the skin[1]. The spectrum of the violet fluorescence contains the typical groups at 427 and 455 mμ of molecularly dispersed benzpyrene. The blue spectrum contains two diffused bands at about 450 and 425 mμ. It is similar to, but apparently not identical with, the fluorescence spectra of 'BPX'[2,3] and the orthorhombic crystalline modification of pure benzpyrene[4]. It is, however, different from the fluorescence spectrum of the monohydroxybenzpyrene which Chalmers and Crowfoot[5] have isolated from the fæces of rats injected with benzpyrene. We have also observed this blue fluorescence in the kidney cortex, liver and lung of mice and rabbits, and in the protein fraction of the milk of lactating mice after injection of benzpyrene[1].

In a new set of experiments the skins of white mice were painted with benzpyrene in acetone and the mice were killed after various periods from ½ hr. to eight days. The skins were then removed, dried and extracted with cold benzene to remove the loosely attached benzpyrene. Fluorescence spectrography of the transparent skins mounted in xylol between slides showed the 'blue' bands from about six hours after painting. They increased in strength until the fourth day and then faded slowly. The dry skins of 1- to 4-day mice were treated overnight with (*a*) 0·01 *N* caustic soda and (*b*) 0·01 *N* hydrochloric acid.

(*a*) The alkaline extract fluoresced blue, while the extracted skin retained some of its fluorescence; after acidifying, the blue fluorescence could be extracted with ether and re-transferred to the aqueous phase by adding fresh alkali.

(*b*) The acid did not show any fluorescence due to benzpyrene, but on extracting the acid-wet skins with ether, blue fluorescence (with weak violet bands deriving from traces of unextracted molecular benzpyrene) entered the ether. The blue fluorescence could be transferred to the aqueous phase with 0·01 *N* caustic soda, and re-transferred into ether after acidifying.

It must be concluded that the blue fluorescence is due to a benzpyrene derivative which is soluble in alkali. It is produced in the painted skins, and persists over periods of several weeks.

We established by low-power microscopy in ultraviolet light that a strong blue fluorescence followed exactly the rows of the hair bulbs. This indicates that the compound is confined to the quickly proliferating cells of the Malpighian layer. It may therefore be of greater importance for the production of tumours than the original benzpyrene itself, especially because this blue-fluorescent compound persists in the skin long after the parent hydrocarbon has disappeared.

Condition of Freshly Burnt Gases

IN his interesting article[1] on "The Condition of Freshly Burnt Gases", Dr. A. G. Gaydon gives very clear expression to his view that during the combustion of dry carbon monoxide mixtures the freshly formed carbon dioxide is charged with a large excess of vibratory energy which is only very slowly partitioned; but if the carbon monoxide mixtures are moist, or a little hydrogen is added to them, partitioning of the excess vibratory energy in the carbon dioxide takes place rapidly because of the powerful deactivating influence of water vapour. Experiment, however, seems to indicate that this view is untenable.

It has been found that the *rate* of emission of infrared radiation measured after (even immediately after) the combustion of reasonably dry carbon monoxide – air mixtures is not greater than that measured after the combustion of similar mixtures in which a little of the carbon monoxide is replaced by hydrogen[2]. Indeed it is rather less, because water vapour radiates more powerfully than carbon dioxide. At all times after combustion, the *rate* of emission of radiation from carbon dioxide, like that from water vapour, would appear to be dominated by flame gas temperature (mean molecular translational energy) and influenced not at all by its previous combustion history.

The question as to whether or not normal gases would luminesce if externally heated to the temperatures usually attained in flames and explosions is one of long standing, and Dr. Gaydon redirects attention to it in his article. He suggests that gases like nitrogen, oxygen and carbon monoxide would not luminesce, and probably there will be general agreement with this view. He thinks, however, that carbon dioxide would luminesce after the fashion of carbon monoxide flame gases on account of the recombination which is continuously taking place after dissociation.

But there is, I think, much evidence for the contrary view, and some of this has been referred to by me in a previous communication[3]. Even more convincing evidence seems to be provided by the flame photographs of carbon monoxide – oxygen explosions taken by Bone and Frazer[4]. The photographs show that when these mixtures are ignited by means of an ordinary spark, the usual luminosity is displayed by the resulting flame gases (for example, photograph No. 19). When, however, they are ignited by means of a very powerful spark, a considerable volume of the gases formed under its influence is dark (for example, photographs Nos. 22 and 23), and this in spite of the fact that an enormous amount of dissociation and recombination must be taking place in them, for their temperature is of the order of 3,000° C.

It is not without interest to observe that the long-tube explosion photographs of Bone and Frazer[5] suggest that flame gases also tend to approach the condition of normal hot gases just immediately after detonation has been set up (see, for example, photographs Nos. 5, 17, 22 and 32).

While Dr. Gaydon's article makes it clear that explanations differ, it is becoming increasingly recognized that the experimental evidence for the existence of a long-lived latent energy in carbon monoxide flame gases is irrefutable. The experimental evidence that it exists in hydrocarbon and hydrocarbon flame gases is, I think, equally irrefutable[6].

W. T. DAVID.

PROF. DAVID refers to his experiments with Parkinson on the rate of emission of radiation from explosions. In this paper I find no mention of any drying process for the gases, or of any attempt to remove adsorbed moisture from the explosion vessel. I therefore assume that the gases were far from dry, and these experiments can scarcely be compared with those of Garner and colleagues to which I referred. They appear to me to support my statement that the concept of vibrationally activated molecules could not explain afterburning or latent energy of long duration in hydrogen-rich fuels. Also I may perhaps be permitted to quote Prof. David's own words relating to some earlier work on coal-gas – air explosions[1], that the "rate of emission of radiation is a maximum about 1/40 sec. before the attainment of maximum temperature". This effect is also very well shown in the curves of David and Parkinson to which Prof. David refers, Curve A in Fig. 2 showing a difference of about 0·03 sec. and Curve B in Fig. 3 of more than 0·05 sec., although for mixtures rich in hydrogen the effect is not observed.

I have shown[2] that the radiative life of the asymmetrical vibration for carbon dioxide is of the order 0·01 sec. and that even in absolutely dry gases the time for equipartition of vibrational energy will be, at most, a few tenths of a second, and very considerably less in the presence of moisture. It is doubtful whether a bolometer of 0·02 sec. period (as used by David and Parkinson) would be adequate for work on moist gases.

With regard to the luminosity of hot gases, I still retain an open mind. I have made it clear in my article and book that the radiation from a carbon monoxide flame is mainly due to chemical causes, and the failure to record appreciable light from hot gases in the neighbourhood of a powerful spark using a very short exposure time proves nothing, except that there is less chemical action taking place. This is probably the result of the pressure wave reducing the time-lag in the equipartition of vibrational energy, and thereby the amount of abnormal dissociation.

I do not feel qualified to express an opinion as to the existence of long-lived latent energy in hydrogen and hydrocarbon fuels. I have already pointed out that there is much apparently contradictory experimental evidence.

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX

SEVENTEENTH ANNUAL CONFERENCE

THE sixteenth annual conference of ASLIB (Association of Special Libraries and Information Bureaux) was planned to be held at University College, Nottingham, in mid-September 1939, but had to be cancelled owing to the outbreak of hostilities; the papers which were prepared for that Conference were afterwards published. The previous Conference had been held at Oxford in 1938 during the Munich crisis. Any idea of holding a succeeding conference in 1940 was rudely shattered by the Battle of Britain, but the comparative lull in the autumn of 1941 encouraged ASLIB to embark on the project of resuming its annual conference in 1942, with the limitation that the principal meeting should be held in London, and the papers there read and discussed should be available for subsequent local meetings in various provincial centres.

The decision to hold the London Conference proved to be very happy, and the generosity of the Royal Society in providing accommodation for the meetings and other functions greatly contributed to the successful outcome. In all, 137 members of ASLIB and visitors attended the several sessions, which occupied the afternoon and evening of November 7 and the morning and afternoon of November 8, and were preceded on the morning of November 7 by the annual general meeting of the Association.

At this meeting, Prof. R. S. Hutton, Goldsmiths professor of metallurgy, Cambridge, was elected president for the ensuing year, in succession to Sir Harry Lindsay, who had served since November 1939. Mr. Theodore Besterman was elected honorary secretary in succession to Mr. Edward Carter, and Mr. E. Lancaster-Jones was re-elected honorary treasurer. At a later meeting of the council, Messrs. Carter and Lancaster-Jones were re-elected respectively chairman and vice-chairman of the council.

The Conference opened at noon on Saturday with a characteristically stimulating address on international systems and standards given by Sir Richard Gregory. The main part of Sir Richard's address is printed elsewhere in this issue (p. 620).

At the first session of the Conference proper, under the chairmanship of Prof. A. C. Egerton, two papers dealing with training in the use of libraries were presented by Mr. C. H. C. Osborne, honorary secretary of the School Libraries Section of the Library Association, and Prof. R. S. Hutton respectively. The former dealt with school and the latter with university libraries, and each indicated the extent to which instruction in the methodology of libraries might be imparted, with mutual benefit to the library and its user. Comparisons of conditions in Great Britain with the practice in other countries, especially in the United States, was deprecated by some speakers in the subsequent discussion, on the grounds that conditions were not comparable. Nevertheless, the feeling was general that more could be done by librarians and educational authorities to educate those who would ultimately have to depend largely upon reference literature in the technique of extracting it from the vast resources of modern libraries.

At the second session, on the evening of November , Dr. Luxmore Newcombe, of the National Central Library, took the chair and the audience listened with avidity to Mr. Besterman's demand for a "Union List of Periodicals in British Libraries". In his customary blend of dogmatic confidence that difficulties were merely so many bubbles to be pricked and experienced skill in deflecting the anticipated missiles of more substantial composition, Mr. Besterman carried his hearers into a calm and purposeful realm of accomplished fact. One had the distinct impression that the Union Catalogue was as good as in one's hands, and some of us who have experienced the tenacity with which its proponent pursues an objective on which he has set his mind had the uneasy conviction that in due course we should be involved in the usual mass of collation attendant upon the production of all Union Catalogues.

Nevertheless, we shall be willing victims, for all of us realize that these monumental contrivances are essential to the ultimate objective of planned economy and efficiency in our national resources of vital reference periodicals. The two editions of the "World List of Scientific Periodicals" have done a great deal in the period intervening between the two World Wars to enable Great Britain to build up its resources, particularly of the more obscure foreign scientific and technical periodicals. Much remains to be done, but all previous Union Catalogues and lists have largely ignored the wealth of reference material that now exists in the various special libraries.

A paper on "Agriculture and the War Stimulus" by Mr. C. S. Orwin, director of the Agricultural Economics Research Institute, had to be taken as read in the absence of its author or any suitable substitute for him.

At the third session, on the morning of November 8, Colonel E. E. B. Mackintosh, director and secretary of the Science Museum, took the chair for a symposium on microfilms, which attracted a very appreciative audience. Mrs. Lucia Moholy, director of the Aslib Microfilm Service, sketched the early uses of microphotography for communication of information in war-time and proceeded to describe the evolution and functions of the Aslib Microfilm Service in the present emergency. To a considerable extent the Service is occupied in photographing on microfilm current issues of foreign scientific and technical periodicals that emanate from enemy or enemy-controlled countries and are received in very small quantities in Great Britain. The microfilms are used to provide additional copies of the whole issues or excerpts therefrom, as required by individuals or institutions having no access to the originals, or desiring their own copies. The necessity for the provision of reading apparatus to enlarge the microfilms to legible dimensions was stressed, as the supply at present available in Great Britain is wholly inadequate.

Mrs. Moholy's interesting paper was followed by one by Mr. E. Lancaster-Jones, keeper of the Science Library, in which the attributes of the microfilm copy of a normal reference book or volume of a periodical, as compared with the original, received detailed consideration. The possibilities of supplementing the microfilm copy by various guides in order to adapt it to facile use by the staff and clients of a reference library were sketched. A further paper by Dr. Vernon Tate, of the National Archives, Washington, D.C., had been promised for this symposium, but was unavoidably delayed in transit. As Dr. Tate's experience of microfilm technique is profound, this was a great disappointment.

In the subsequent discussion on the two papers, many helpful remarks were made upon the provision of reading apparatus by the adaptation of available mechanisms, such as cinema projectors, to the purpose, and there is no doubt that those individuals who possess the skill and equipment to carry out the minor constructional modifications needed can produce a reasonably efficient machine for enlarging the films, certainly for the purposes of individual research. But one has only to handle an efficient commercial reader, specially designed for the work, to realize that its construction is the result of long experience of the problem, and the results are very satisfying. A small exhibition of reading apparatus, arranged by the Aslib Microfilm Service, proved very popular and instructive.

The final session of the Conference, under the chairmanship of Mr. T. R. Dawson, of the Research Association of British Rubber Manufacturers, was devoted to a paper by Mr. J. E. Wright of the Post Office Research Station on "Some Methods used in the Special Library of a Research Department", followed by one on "War-time Books and Periodicals : some Suggestions", by Mr. B. M. Headicar. Mr. Wright's paper was not merely an account of the methodology of the particular library of the Post Office Research Station, but also contained a rich fund of information and suggestions adapted to use by any similar library; a series of clues to specific requests for information was perhaps the most interesting and instructive section of the paper. Mr. Headicar dealt in his customary adept manner with a multiplicity of practical details, including suggestions for economy in paper and binding; he illustrated his address by greatly appreciated practical demonstrations of the methods recommended.

SEASONING OF TIMBER

By ALEXANDER L. HOWARD

Necessitas non habet legem ("Piers Plowman", 1377).

WHILE it is true that the harsh dictates of necessity have resulted in many discoveries and useful practices in the seasoning of timber, laws regarding the process are adamant; and although simple, the principles which govern the procedure are unalterable. The sap and moisture contents must be drawn out of the wood and the necessary methods employed to bring the wood to that degree of moisture content desired. The process must be varied according to the species of timber and the purpose for which it is required.

Never in the history of Great Britain has this question been of such vital importance as it is to-day. Commodities of all sorts—food, delicate instruments, ammunition, and war material of all kinds—must be packed safely for transport over great distances and under trying conditions, and it is essential that the cases used for this purpose can be relied upon to preserve their valuable contents.

Of those materials which can be used, timber plays the most important part. We are forced to rely to a very great extent upon available native timber, which could be put to better use if adequate facilities for seasoning existed.

It has been proved that timber of many kinds, and in the dimensions required, can be seasoned in a satisfactory manner in a short time, and indeed there are already many established kilns fully occupied and successfully working, but in no sense sufficient for the demands of total war. Even though it involves great expense and effort, many more drying kilns of efficient design should be established as quickly as possible to make good this deficiency.

Fortunately, the lessons of the War of 1914–18 and scientific research have enabled us to overcome all the main difficulties, and the chief problem that concerns us is no longer the method to be employed, but the establishment of sufficient kilns throughout the country.

The primary object is to create within the kiln a continuous and regular current of air (at first charged with moisture) to suit the condition of the unseasoned or fractious wood, and then to withdraw the moisture and introduce the heat by carefully controlled degrees, until the desired percentage of moisture contents has been acquired. To accomplish this, it is essential that every square inch of the timber should be subjected to an equal volume of the current, and while the dimensions of the kiln play an important part, by far the greater importance lies in the scientific application of the correct combination of moisture and heat.

During the course of the last hundred years, innumerable processes have been tried out, many of which have been patented but later abandoned Among these systems is a process which might be described as a 'bakery'—that is, one in which the timber is placed in a compartment somewhat similar to an oven. Other ingenious systems have been tried in which the wood is subjected to a vacuum, with water and steam introduced later. Another process has been to place the timber in boiling water accompanied by the introduction of saccharine or other ingredient, and a still further attempt has been made by the use of an electric current. Most of these, or perhaps all, have been abandoned, at least so far as commercial practice is concerned: at another time and in more easy circumstances, it would be desirable to enter into further scientific research, which migh give us more information and thus secure even bette results. At present our endeavour should be to concentrate our attention towards providing that which we know can secure an immediate as well as a satisfactory result.

Two methods are available, which are what are known as the 'progressive' and the 'compartment kilns, both well understood and universally accepted

For large quantities of box boards the progressiv method would probably be efficient, but this system would not succeed when applied to the more fractious and difficult woods, when the compartment system should be adopted.

In the progressive kiln the wood is placed o trucks, allowing sufficient air space between the boards. The trucks are moved under control throug successive chambers which have been prepared wit the necessary saturation of moisture and the introduction of dry heat. The moisture contents ar gradually withdrawn and the dry heat increased On completion, the charge is found to contain that correct percentage of moisture contents which was calculated as ordered.

In the compartment system, as the name implies the timber is piled with similar air ventilation, bu in a fixed chamber where moisture and heat are introduced. As in the case of the progressive kiln the moisture is gradually withdrawn and the hea increased, so that after the necessary period, which varies according to the description and thickness of wood, whether fractious or kindly, the chamber may be opened and the charge will be found to conform to any given degree of moisture contents stipulated. Complete reliance can be placed on either of these methods.

The outlay required to provide an adequate number of such kilns throughout Great Britain will, of course, be heavy, but having regard to the urgency, this consideration ought to be of secondary importance.

An ample supply of properly seasoned timber for the boxing and safe transport of the vital necessities of war is essential to our war effort, and until this question has been adequately dealt with we may suffer serious losses, not only financial but also endangering the health and welfare of our troops and those of our Allies.

NEW AND LITTLE-KNOWN FISHES

THE *Stanford Ichthyological Bulletin*, published by the Natural History Museum of Stanford University, is responsible for many valuable descriptions of fishes, and the two numbers before us 2, No. 4, Aug. 24, No. 5, Aug. 31, 1942) contain various papers, the most striking of which are George G. Myers's "Studies of South American Freshwater Fishes" and Albert W. C. T. Herre's "New and Little Known Phallostethids, with Keys to the Genera and Philippine Species". The Natural History Museum of Stanford University has amassed a large collection of South American fishes, which, together with the very extensive South American material in the California Academy of Science, forms probably he finest series available anywhere for the study of South American fluviatile ichthyology.

In the present work are included fishes from Amazonian Peru, from Venezuela and from Rio de Janeiro. Especially interesting is *Hoplomyzon atrizona* n.g. et sp., a new Bunocephalid from Peru, which is armed with a series of bony plates along the body, and apparently has no close relatives. It is adapted for life in swift water and the head has maxillary barbels strongly resembling some of the ill-stream Nematognaths.

Many new Cyprinodonts were collected by Lieut.-Col. and Mrs. White in the coastal plain of the State of Rio de Janeiro, their object being to study them in their own aquaria. Fishes of the genus Cynolebias re favourites with aquarists and are known to be annual fishes with a full life-cycle within one year. They are usually found in isolated water holes, swamps and ponds which dry up in the dry season, only the eggs surviving in the mud. After hatching in the wet season, development of the fry is rapid and in some instances full growth is attained in two or three months. The species of this genus, wing to their specialized habitat and seasonal occurrence, are seldom seen by ordinary ichthyologists and are usually only obtained through commercial aquarium fish collectors. The present eries is therefore specially valuable. It includes many new forms of these very beautiful small fishes hich in life are brilliantly coloured. Five of the new species are described and notes given from olour sketches made from the living material.

Herre's paper on the Phallostethids describes many of these peculiar fishes, which are all very small and almost transparent with very little colouring. The sexes are strongly dimorphic, the male possessing a special bony organ lying on the outside of the head which serves for clasping the female. Eighteen species are so far known, occurring in brackish and salt water in Malaya, Singapore, Siam, Borneo and the Philippines, in mountain brooks in Luzon and lowland freshwater creeks in Siam and Luzon, and in freshwater lakes from the Philippines and off Sumatra. It is expected that many more are yet to be discovered.

SCOTTISH LAKE DWELLINGS*

FOR the first time one of the very numerous artificial islands on the Scottish lochs has been examined with a technical skill comparable to that so profitably expended on the crannogs of Somerset and more recently of Ireland. Fortunately, the engineers in charge of the Lochaber Water Power Scheme appreciated the scientific importance of the crannog in the north end of Loch Treig that the scheme had exposed and would destroy. Still more fortunately Prof. Ritchie, then at the University of Aberdeen, was able to take advantage of the opportunity for a thorough investigation of the island's structure.

The crannog proved to differ both in plan and construction from the Glastonbury lake village and the individual lacustrine habitations explored by Munro in Galloway last century and more recently by Hencken in Ireland. While the latter are round, it was rectangular. The basal structure was a framework of squared beams, 65 ft. by 42 ft., founded upon a bed of large stones that had been laid on a natural elevation in the loch floor. Above this, layers of timbers and, of earth and stones, each separated by layers of brushwood, birch-branches or heather, and in all nearly 6 ft. thick, supported an upper framework of undressed trunks 57 ft. long by 30 ft. broad. It supported yet another layer of brushwood, above which came the actual dwelling floors, frequently renewed until the total deposit above the upper platform was 3 ft. thick. The timber frameworks were kept in place by a double row of upright piles that the excavator shows cannot have served as a defensive palisade.

Access to the island was not provided by any causeway, but a landing stage was found from which a sloping ladder led up to the island's surface. The report emphasizes the structural importance of the brushwork layers both in distributing the weight of superstructures and in cementing together heterogeneous layers.

Ritchie argues convincingly that the usual accounts of the construction of such islands simply will not work with the Treig crannog, and concludes that its builders must have temporarily lowered the water-level at this end of the loch. Relics were disappointingly scarce. They confirm literary testimony to the occupation of the island in the sixteenth and seventeenth centuries, but nothing unambiguously distinctive of an earlier period was found, though a leather shoe seems to be derived from a Romano-British pattern, and the peculiar technique exemplified in a woollen fabric finds its nearest (but still not exact) parallel in textiles of the Viking Age.

---

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Saturday, November 28

Royal Photographic Society (at 16 Princes Gate, South Kensington, London, S.W.7), at 3 p.m.—Dr. S. O. Rawling: "Sensitometry since Hurter and Driffield" (Hurter and Driffield Memorial Lecture).

Monday, November 30

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. W. Allen: "Some Aspects of Insulation", 2: "Sound Insulation" (Cantor Lectures, 2).

Royal Society (at the Royal Institution, Albemarle Street, London, W.1), at 3 p.m.—Lectures in commemoration of the Tercentenary of the birth of Isaac Newton. Prof. E. N. da C. Andrade, F.R.S.: "Newton and the Science of his Age"; Rt. Hon. Lord Rayleigh, F.R.S.: "Newton as an Experimenter"; Sir James Jeans, O.M., F.R.S.: "Newton and the Science of To-day".

Tuesday, December 1

Institution of Civil Engineers (at Great George Street, Westminster, London, S.W.1), at 2 p.m.—Mr. J. K. Hunter and Mr. R. W. Mountain: "Hydro-Electric Development, some Economic Aspects".

Royal Institution (at 21 Albemarle Street, London, W.1), at 3 p.m.—Prof. J. C. Drummond: "The History of our More Important Foods", (ii) "Meats".*

Wednesday, December 2

Royal Society of Arts (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. D. R. Bomford: "Agriculture To-day and To-morrow", 2: "Machinery in Modern Farming".

British Society for International Bibliography (at the Science Museum, Exhibition Road, South Kensington, London, S.W.7), at 2.15 p.m.—Mr. R. Unwin and Mr. M. C. Haycroft: "Cooperation between Authors and Printers in the Preparation of Copy for Publication".

Royal Entomological Society of London (joint meeting with the Genetical Society) (at 41 Queen's Gate, South Kensington, London, S.W.7), at 3 p.m.—"Methods of Study of Wild Populations" (Speakers: Dr. R. A. Fisher, F.R.S., Prof. Julian Huxley, F.R.S., Dr. C. B. Williams, Dr. George Salt, Prof. P. A. Buxton).

Thursday, December 3

Institution of Electrical Engineers (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Lieut.-Colonel K. Edgcumbe: "Standardization as applied to Industrial Electrical Instruments".

Friday, December 4

Royal Institution (at 21 Albemarle Street, London, W.1), at 5 p.m.—Prof. William G. Holford: "The Small House and the Large Town, some Town Planning Problems".

Physical Society (in the Lecture Theatre of the Science Museum, Exhibition Road, South Kensington, London, S.W.7), at 4.30 p.m.—Prof. E. N. da C. Andrade, F.R.S.: A lecture on Newton (in celebration of the Tercentenary of Newton's Birth).

Saturday, December 5—Sunday, December 6

Association of Scientific Workers (with the support of the British Association) (at Gas Industry House, 1 Grosvenor Place, London, S.W.1)—Conference on "Scientists of the United Nations and the War Effort".*

Saturday

At 2.30 p.m.—"Allied Scientists" (Chairman: Sir Richard Gregory, Bart., F.R.S.).

Sunday

At 11 a.m.—"Free National and Refugee Scientists" (Chairman: Prof. John Marrack).

At 2.30 p.m.—"British Scientists" (Chairman: Sir John Russell, F.R.S.).

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer (man or woman) for Chemistry and Physics, and a Lecturer for Engineering Subjects—The Principal, Shrewsbury Technical College, Shrewsbury.

Headmaster of Felsted School—The Clerk to the Governors, Mr. Norman Orfeur, Solicitor, Braintree, Essex (December 31).

Director of the National Froebel Foundation—The Secretary, National Froebel Foundation, 2 Manchester Square, London, W.1 (February 27).

SCIENCE AND THE WAR EFFORT

THE eighteenth report of the Select Committee on National Expenditure is concerned with 'a number of those questions relating to the scientific side of the war effort which were raised in the Select Committee's own eighth report on the organization of production, and which the new arrangements and appointments by the Minister of Production were designed to meet. The report is an acute analysis which, if it does not entirely dispel the anxieties of scientific workers, should assist to focus constructive criticism on the weak points of the present structure. It records the general impression that if the steps taken in recent months are properly followed up and the right men found to fill the key appointments, war efficiency should be improved in the vitally important matter of providing the Fighting Forces with the right weapons at the right time.

Considerations of public safety have limited the Committee to observations in general terms on the main principles of organization necessary and on specially important features in executive methods. In regard to the clarification of responsibilities, it is pointed out that the key questions are exactly where, under the new arrangements, the responsibility rests for formulating the Army's requirements and the manner in which the practical arrangements on the War Office side for formulating requirements link up with the arrangements on the Ministry of Supply side for converting these requirements into production of suitable weapons. On this it is observed that, while the answer to the first question is that the responsibility under the Secretary of State and the Chief of the Imperial General Staff is now centralized in the Deputy Chief of the Imperial General Staff, for practical purposes there must be a very clear understanding as to the nature of the responsibility carried by each of the officers, directorates or committees on which he relies.

In regard to the functional organization of research, design and production, the Committee points out that the conception of a unified functional organization requires application beyond the armoured fighting vehicles. Moreover, the Committee's realization of the vital importance of fully utilizing all available resources in the application of scientific research, technological skill and inventive intelligence to the production of improved new devices for fighting the enemy has led it to make a further inquiry into the organization on the Government side for handling the work of research, design and development. The observation that the success of new arrangements depends above all on the right men being chosen to fill the new posts as well as on the spirit in which Ministries and branches co-operate, for all its general applicability, should therefore not be taken as implying criticism of the three scientific advisers recently appointed to Mr. Lyttelton's staff to complete the organization for scientific research and development.

The main observations of this report deal with the relations between the Government organization and manufacturing industry. While research, development and detailed designing will now, so far as possible, be carried out by parent firms in full co-operation with the Ministry of Supply, the Committee suggests that in the design of instruments of war the responsibility for checking the battle-worthiness of a design and for ordering production to go ahead must always remain entirely with the Government authorities, as well as the responsibility for giving drive and urgency to the creation of a good technical design for a defined purpose. The responsibility for creating such a design, which involves individual qualities of originality and imagination, must on the other hand be handled in close contact with those who have to carry out the task of production.

The measure of responsibility that can properly be delegated to a private firm must largely depend on its character and organization. Normally, the combined responsibility for working out a design and for taking the lead in production as the parent firm of a group should be restricted to firms of stability and proved capacity, with substantial resources and good organization. Moreover, in regard to experience and resources, such close and confidential relations must be reciprocal, and all the technical data and results be placed at the disposal of the Government; there is an implied obligation to work essentially as part of the machinery of Government rather than in the spirit of private concerns. Sometimes the exchange of information and Government assistance appear to be haphazard, particularly when contracts are distributed among a number of firms with no previous experience in the operation of the necessary processes. Certain groups seem to be left without definite leadership, and in other cases where an individual engaged on Government research work may have found means to make contact with manufacturers, the value and extent of his assistance could be greatly increased by strengthening his own staff. The Committee recommends a systematic review of the working of the existing groups, and that the continuance of contact with such groups should be made the responsibility of a special officer or officers.

Scientific workers, while somewhat re-assured by the present report, will undoubtedly await with great interest the result of the further inquiry now proceeding. Reverting to the remark made above that the success of the new arrangements for scientific guidance made by the Minister of Supply (see NATURE, September 12, p. 301) depends on the right men being chosen for the key posts, the question of the position of Sir Stafford Cripps naturally arises. With his appointment as Minister of Aircraft Production, he has to bear the responsibilities of the administration of a Department of crucial importance in the struggle. Hence it is scarcely likely that he will be able to devote detailed attention to the activities of the new scientific advisers, and since he is no longer a member of the War Cabinet, he cannot present their views to those who are directing the War. Yet one of the reasons for welcoming the appointment of the three full-time scientific advisers to the Minister of Production was the further statement that they would "work under the immediate supervision of the Lord Privy Seal [Sir Stafford Cripps]" acting on behalf of the Minister. The position is not clear at present, and will be watched by scientific workers and others with keen attention.

CIVIL DEFENCE AGAINST WAR GASES

WAR has always been horrible. Axe and sword, lance and dagger gave way to gunpowder, though it did not entirely displace cold steel even in the Crimean war; to-day we depend largely on high explosives. During the War of 1914–18 there befell a new horror—chemical warfare, the use of poison gases—which shocked the world. When peace came, the nations solemnly renounced the use of gas at a Geneva conference, a pledge which has so far been kept—nor is there any reason why it should be broken. None the less, the defence against chemical warfare has to be ready. Thus everyone in Great Britain has a gas mask and knows how to use it and care for it. In addition, a highly organized and well-trained gas service has been brought into being, ready to function when required, though hopeful that enough of civilization remains to spare the world this particular horror.

The defence against gas has the advantage over the defence against high explosive or fire bombs that it can be complete. Knowledge of what to do and the ability to do it quickly can make the individual safe in the heaviest gas attack. The value and the efficiency of the general civilian and other official types of respirator cannot be too highly rated. These respirators will stop all the likely war gases and even the strongest concentrations which can be produced in the immediate vicinity of bombs out of doors. They will remain completely effective against lesser concentrations almost indefinitely. It is the duty of men of science to make clear to their lay friends that they can have complete confidence in their respirators.

The other danger to the public is that due to splashes of vesicant gases or prolonged exposure particularly of the eyes, to vapour from these. The area splashed by any one bomb is small, and in general the number of people likely to be splashed on its bursting will not be large. Should one become a casualty, the skin must be treated without delay with the ointment which has been prescribed for the purpose. In addition, should gas be used, chemists' shops will have pails of bleach cream ready for use by persons who may not have ointment immediately available. The clothing must be shed at once so as to prevent penetration of liquid and vapour to the skin. The Ministry of Health has made ample arrangements both for personal cleansing and for decontamination of clothing. Above all, it is important to keep the eyes shielded should a gas attack be feared.

The vapour danger from vesicant gases, which exists until the liquid in the streets has been destroyed, depends upon the concentration and the time of exposure. This danger is therefore also a function of temperature, which governs the concentration, and so is less at night. Under ordinary conditions the time required to produce blistering effects on the skin may be as much as an hour or more. There is, therefore, no need to run this risk by remaining so long in the vapour. Vesicant burns are highly undesirable wounds, but they can be largely avoided by the exercise of commonsense.

No branch of the national defence has been more fully or precisely documented than gas. The Government has enlisted the help of some of the ablest scientific men of the country to aid the official chemical defence organization in the preparation of a series of A.R.P. handbooks. These were ready from 1936 onwards and have, where necessary, been kept up to date by new editions. The information given in these represents the considered conclusions of many who have thoroughly studied the subject in a practical manner; the handbooks are cheap, and they form the basis of the instruction given to an increasing number of pupils in the A.R.P. training schools. Numerous books on the subject have also been published; at the best these are but copies in altered wording of the official handbooks and, where in them an author chooses to air his own views, he runs the risk of being at variance with those who have been in a position to make experiments.

A gas attack may have several consequences: it may injure the individual or contaminate his clothing and surroundings, or it may contaminate foodstuffs, rendering them unfit to eat. This last aspect is a special one, and in view of its importance and the need to prevent any waste of food, it has received full official appreciation and study. The problem involves recognition that a foodstuff may have been contaminated, a task performed by the Gas Identification Service; the determination of the degree and extent of the damage by the analyst; and the decision whether the material must be destroyed or can be decontaminated and made fit for consumption.

It is necessary and proper to create and train an organization ready to cope with gas-contaminated foodstuffs, however great the emergency. There is a tendency, however, in certain quarters to exaggerate this danger. It is highly unlikely that gases or vapours themselves will harm most foodstuffs, and since the majority of foods are stored inside buildings and are themselves in packages, splashing or liquid contamination is not likely to be a frequent occurrence. It is arsenical contamination which gives most cause for precautionary measures. It is possible that gas bombs may fall in water reservoirs. Such incidents have to be studied from the point of view of the volume of the reservoir in relation to the volume of the bomb, and may be regarded in general as of small significance in making water unpotable.

It is sometimes overlooked that any gas brought to Great Britain from a foreign country has to be carried in aeroplanes, which are limited in numbers and have a restricted load. Calculations which can readily be made indicate that the maximum possible amount of gas that can be dropped in a given time is very small in relation to the total volume of air over, and total extent of ground-space in, the area attacked. Hence its effect may be expected to be local rather than general, and limited in magnitude. There can be no such thing as a lake of gas persisting over a large area, or a whole city soaked in gas.

To-day the ordinary citizen has a good deal to think about and it may be unfair to expect that, while he regards the use of gas as improbable, he will take a keen interest in his personal defence against gas. There must be no slackening, however, in the effort to train the A.R.P. key men in gas defence, for it cannot be too strongly emphasized that a highly perfected defence against gas is the best means of ensuring that poison gas will not be used against our cities, since such an attack can then have little success. It is obviously impossible to do more than express the view that this work is being well done.

The problems confronting the authorities during and after a raid in any 'target area' are likely to be many and varied. It is to be supposed, for example, that gas bombs will be mixed indiscriminately with high explosive and incendiary bombs. The available resources, growing more scanty as the need for men for the Armed Forces gets more pressing, will have to be deployed to the best advantage, while those in the control rooms will need to be able to appreciate the significance of any happening and to take measures to allay panic and meet the situation. Gas being a weapon, unknown and unseen, may well cause panic unless men with the qualifications of the gas advisers and gas identification officers are available in the control centres and able to reduce the imaginary to the actual danger. The task of such officers is to correlate the mass of evidence from incoming reports, advise in regard to contradictions and anomalies, and generally keep the incident on a sane and sober basis.

The planning of exercises on a large scale is an important part of the training of the senio officers. All the different units concerned learn to know one another and to work together. Such exercises go beyond the actual attack by gas on the people and their homes; they comprise also the rescue of contaminated food, the making safe of streets splashed with mustard gas—an operation which can now be done in relatively few minutes—and the decontamination of the individual room in a house which has received a direct hit.

By such training and preparation, which are part of the normal experience of the Armed Forces, the civil population can be guarded against the effects, subjective as well as objective, of gas attack. Given effective protection, as scientific men will readily appreciate, gas attack can achieve little success; the knowledge that an adequate defence service against gas is in operation will be a major factor in deterring the enemy from using it.

MATRILINY IN INDIAN SOCIETY

Mother-right in India

By Baron Omar Rolf Ehrenfels. (Osmania University Series.) Pp. xi+229. (London: Oxford University Press, 1941.) 12*s.* 6*d.* net.

BARON EHRENFELS has undertaken an ambitious scheme in his analysis of mother-right in India, and that is no less than to investigate "the entire complex of problems grouped round the questions of the matriarchal system in India". The results at which he arrives are far-reaching. He concludes that in the south-west, if not in the main peninsula, of India there have been four strata of matrilineal peoples, while a fifth is to be found in the north-east. A map indicates the distribution all over India of more or less isolated features of these matrilineal cultures, which survive as complete and functioning matrilineal societies only on the Malabar coast in the south-west, and in the Khasia and Garo Hills in the north-east. To the influence of these matrilineal cultures of the past, of which traces only now survive in the greater part of India, Baron Ehrenfels attributes a very large number of past and present features of Indian society. Thus the efflorescence of Buddhist culture in the fifth, fourth and third centuries B.C., the practice of vegetarianism, the widespread, if socially despised, institution of the matrilocal marriage in which the son-in-law goes to live as a *ghar-jamai* in the house of his sonless father-in-law, and many familiar features of Rajput society past and present, such as the practice of *johar*, that is, the immolation of themselves by the women *en masse* when their men were defeated in warfare, and the continuing use of cattle in marriage processions, are all put down to the influence of the fourth matrilineal culture, which is held to have flourished at Mohenjodaro, while megalithic cultures, head-hunting, and the practice of sacrifice by decapitation, for example, are ascribed to an earlier and more primitive stratum of matriliny. Other institutions again, child-marriage, hypergamy, bride-prices, are directly ascribed to the clash of immigrant patrilineal with pre-established matrilineal cultures, while totemism is regarded as the pure product of a patrilineal age.

It can scarcely be said that the author makes an entirely convincing case for all this. Wide as his research has been, the very nature of the evidence is such that its interpretation can only rest on inference, and alternative hypotheses cannot be excluded. For one thing Baron Ehrenfels belongs emphatically to the *Kulturkreise* school of Schmidt and Graebner; Father Koppers, indeed, has written a preface to his volume. Not everyone will be willing to attach the same importance as that school attaches to migrations of peoples as the agents in spreading cultures, for it is easy to show that ideas, languages and social customs can be diffused no less widely than material culture without any movement of population. In any case an attempt to deal with Indian cultures on such lines ought not to have ignored, as Ehrenfels has done, the significant distribution of brachycephaly in India; and one may legitimately take exception to the use of the terms 'Aryan' and 'Dravidian', which are purely linguistic terms, as if they had a satisfactory racial significance. The essential continuity of traditional and popular Hinduism with the pre-Rigvedic religion of India has not been appreciated. This religion conquered that of the Rigvedic invaders and reduced their high god, Indra, to a mere door-keeper. Thus the Black Yajurveda prescribes the sacrifice of cattle to a number of Rigvedic deities, but not to Shiva, whose cult goes back to the Indus civilization; later the Aditya Purana prohibits the sacrifice of cattle "because certain noble and wise men did not practise it"; while a later authority still states that although their flesh may fitly be offered to Mitra and Varuna they should not be sacrificed, because the public detested it. Marshall's arbitrary distinction between the bull cult of Mohenjodaro and a cow cult ascribed to the 'Aryan' invaders has, of course, no sort of validity, and should not have been accepted. Ehrenfels follows Heine-Geldern in identifying the short-horned bull on the Indus seals with the gaur, an identification the reviewer is inclined to accept, but it must be pointed out that both Friederichs and Olver identify it with either *Bos primigenius* or *Bos namadicus*, Olver specifically rejecting any identification with *Bos gaurus*. There are some regrettable omissions in the material surveyed. The people of the Simla hills, and the Khasas and Hill Doms of the United Provinces, with their many survivals of matriliny and of the worship of snakes and a mother goddess do not appear at all, nor do a number of the Assam tribes, the Lakher in particular, which retain striking survivals from matrilineal cultures.

Whatever its defects, however, "Mother-right in India" is a work of much importance to Indologists, particularly in its suggestive ascriptions of so many features of Indian culture to a clash between an established and more or less civilized matrilineal society and an invading patrilineal one. In this respect Baron Ehrenfels has hit on an important and even fundamental element in the construction of Indian society as we know it now. The reviewer has himself suggested that the social grading of castes in the Laws of Manu has a similar origin. The offspring of a Brahman man and a woman of lower status may stand socially near the top of the list; that of a Brahman woman by a man of low caste comes at the very bottom. It seems likely that this scheme is the formalist interpretation at a later date of the conditions and traditions surviving from a time when the issue of a marriage between a patrilineal man and a matrilineal woman inherited status, if not property, from both sides, whereas the offspring of a patrilineal woman by a matrilineal man would have neither status nor inheritance on either side. The Brahman doctrine that the woman is a mere soil for the reception and nourishment of the seed of the man, to which she contributes nothing essential of her own, is the sort of simple and plausible idea that might easily appear to be the sudden revelation of a profound truth among uncritical peoples observing matrilineal customs without perhaps laying any particularly marked emphasis on the part played by the male in procreation, and one can imagine the spread of such an idea with devastatingly revolutionary effects on culture. It is perhaps rather to some phenomenon of this kind that we should look for an explanation of the inconsistencies of Indian culture patterns than to an application of the culture-strata theory of the Vienna school. But the material for study remains constant and much of it has been collected and collated for us by Baron Ehrenfels.

J. H. HUTTON.

MATERIALS FOR STUDENTS AND DESIGNERS

Strength of Materials

By Prof. S. Timoshenko. Second edition. Part 1: Elementary Theory and Problems. Pp. xiii+359. Part 2: Advanced Theory and Problems. Pp. xiii+510. (London: Macmillan and Co., Ltd., 1940–1941.) 2 vols., 50s. net.

IN 1938 a remarkable tribute was paid to Prof. Timoshenko on the occasion of his sixtieth birthday. Advantage was taken at the annual dinner of the American Society of Mechanical Engineers to honour him by a programme of appreciative speeches and to present to him a commemorative volume in which original articles, dealing with various aspects of the mechanics of solids, had been contributed by engineering and scientific friends each with an international reputation. It is not surprising, therefore, that text-books from Prof. Timoshenko should be welcomed by all interested in the progress of engineering learning.

The present review deals with the second edition of his now famous work on the strength of materials. This is divided into two volumes, the first of which is devoted very largely to the presentation of matter usually taught in engineering degree courses dealing with the strength of materials. For post-graduate students and research workers the second volume will be found particularly suitable, since it deals with those difficult features of engineering design and investigation which all engaged in engineering production must, at some time, inevitably encounter.

Although no great changes have been made in this second edition, yet where experience has shown that teaching requirements may be better met, modifications in the methods of presentation have been adopted and some of the more advanced work, originally contained in Part 1, has now been transferred to Part 2. In place of this advanced matter, a more extended treatment has been given in Part 1 to some of the problems previously expounded rather briefly, with the result that the student will now read these with greater understanding.

Space will permit of only a brief reference to the contents of these volumes, but some attention may be given to a few features. Thus the admirable arrangement of Chapter 1, dealing with tension and compression within the elastic limit, can be especially commended. Here the student is gradually led from the most elementary consideration of stress and strain up to the solution of quite difficult problems by a skilful blending of descriptive matter and excellent examples. In like manner, the method of dealing with the deflection of loaded beams calls for admiration. Commencing with the equation of the deflection curve, the usual integration method of determining deflection of cantilever and simply supported beams with different types of loading is first employed, and here again the arithmetical examples provided are particularly suitable. This is followed by illustration of the use of the bending moment diagram and the method of superposition, whereby the solution of difficult problems under complicated systems of loading and different methods of support can easily be effected. Later on, the elastic strain energy method is given and attention directed to considerations of the effect of shear. In all this fundamental work, the manner in which the student is conducted from the simple to the more complicated problem is a great tribute to the powers of Prof. Timoshenko as a teacher.

In Part 2, special attention is given to the later developments, both theoretical and experimental, of practical importance in the fields of strength of materials and theory of elasticity. Problems connected with aeroplane construction are considered under the investigations into the bending, compression and torsion of slender and thin-walled structures. A chapter is devoted to plastic deformation and another to experimental investigations on the behaviour of materials at high temperatures and to fatigue under conditions of stress reversal.

Although for much of the work in this volume a fairly high standard of mathematics is required, yet the author never omits to place the practical engineering considerations before the reader, and continual references are made to original papers on the subject under discussion. Thus, following the mathematical treatment of stresses produced by shrink fits, attention is directed to special articles dealing with experimental investigations into this class of engineering construction. It is suggested here that some mention might have been made of the work of Russell, who showed experimentally that the effectiveness of the shrink fit largely depends upon the surface cleanliness of the two mating elements.

One difficulty to British students will arise from the author's use of symbols which differ appreciably from those employed in our own text-books. In this second edition, changes have been made in the notation to conform with the requirements recently adopted by the American Society of Mechanical Engineers. It is to be hoped that it will not be long before a standard list of symbols will be drawn up which will be common to both countries.

WEATHER STUDY

Weather Study

By Prof. David Brunt. (Nelson's Aeroscience Manuals.) Pp. 216. (London and Edinburgh: Thomas Nelson and Sons, Ltd., 1942.) 5s. net.

WAR has always been very much at the mercy of the weather, and the advent of flying emphasized the dependence. Between 1914 and 1917, meteorology gradually came to be an essential part of the fighting organization, though the scientific side of the work was still in the hands of a relatively few professionals. In the present conflict some knowledge of the subject is essential, or at least helpful, to a large number of 'other ranks', while the number of civilians engaged on work in which the physical processes of weather are directly or indirectly involved must run into thousands in Great Britain alone. These men and women, mostly young and intelligent but with little specialized training, are eager to learn; yet the range of suitable text-books open to them is sadly limited. Hence Prof. Brunt's new semi-popular book, written explicitly for this class of reader—he mentions in particular Air Force Cadets and students of radio-location—is very welcome.

The emphasis on weather study has shifted very definitely from the descriptive to the analytical side, and especially to the physics of weather. The early meteorologists were for the most part content to explore and describe the facts in terms of averages and extremes of temperature, rainfall, etc.; the moderns seek to explain them in terms of air-masses, fronts and lapse-rates. But the physical meteorologist requires more rather than fewer observations, and the first requisite for the young meteorologist is a thorough knowledge of the instruments and methods of observation. This is the subject of Chapter 1, which might usefully have been twice the length. For example, although the units of pressure and temperature, and the various corrections to the barometer reading, are set out in some detail, the vernier is barely mentioned, and the reader is not warned at all against such errors as parallax. It would have been better to have given a definite reference in the text to the "Meteorological Observer's Handbook" rather than to leave it to the appendix, and for less ambitious readers, mention might be made of "Hints to Meteorological Observers". One cannot but feel that Prof. Brunt is not really interested in such mundane details, but is anxious to get on with the meteorology.

The rest of the book on the whole meets the criterion "not too little, not too much" very well. In Chapter 2 the author plunges boldly into what is probably the most general immediate cause of most weather phenomena, the diurnal variation of air temperature near the ground and its variation with height, with the corresponding phenomena of inversions and super-adiabatic lapse-rates, though adiabatic changes are not actually explained until a later chapter. Then follows a very brief account of world climatology, in which *causes* take wise precedence, the more striking facts only being used as examples (incidentally, the statement that in India the monsoon rainfall amounts "in places at times to several hundred inches within one month" might give an exaggerated impression; the two recorded instances of falls exceeding 300 in. in a month are both doubtful).

The core of the book is reached in the chapters dealing with the elementary physics of the atmosphere, including adiabatic changes of dry and saturated air, conditions in the upper air as represented by tephigrams and similar diagrams, the effects of radiation, and water vapour in the atmosphere. The remaining chapters consist of an introduction to the study of synoptic charts, decoding and plotting the observations, drawing the isobars and interpreting the charts in terms of gradient and upper winds and air masses. Depressions, both frontal and non-frontal, are described in some detail, but the account of thunderstorms is meagre; considering that the book is specifically dedicated to, among others, students of radio-location, one would have expected to find some reference to atmospherics, and even to the ionosphere.

On the whole, the book fulfils its purpose admirably. Though mildly mathematical in places, it is rarely difficult, and the more abstruse sections are well provided with clear diagrams. There are inevitably some blemishes; for example, the odd breaks in the diagram of relative humidity in relation to dry- and wet-bulb readings should have been explained as due to the coating of the wet-bulb with ice, and in the equations of change of pressure with height some confusion is caused by using *d* for the differential and for density in the same equation. Later, a curve stated to be the barograph curve of a sailplane flight is described as "rising or falling as the aircraft met rising or descending currents". These are minor points; more serious is the fact that the map of prevailing winds in July has suffered some sea-change and is about as wrong as it could be, showing, for example, sweeping *easterly* winds in the temperate latitudes of the southern hemisphere.

It is most unfortunate that lack of attention to detail and proof-reading should have marred what is in most respects an excellent book, for any reader who has dealt with it faithfully and written out answers to the test questions at the end of each chapter may fairly consider himself on the way to becoming a proficient meteorologist.

C. E. P. Brooks.

THE FALLING BIRTH-RATE

Parents Revolt

A Study of the Declining Birth-rate in Acquisitive Societies. By Richard and Kathleen Titmuss. Pp. 128. (London: Martin Secker and Warburg, Ltd., 1942.) 3*s*. 6*d*. net.

THIS book, which comes with a commendatory foreword by Beatrice Webb, is the work of writers well versed in the comparatively new but vigorous science of demography. As its title clearly intimates, however, its aim is not academic but practical. Demography has made rapid progress since the War of 1914–18. Its new and exciting discoveries, say the writers, though of vast importance to the future of man, are practically unknown to the general public. What the general public does know is that the practice of birth control, by means of devices for preventing conception, has spread from the well-to-do classes, among whom it arose in the closing decades of the nineteenth century, to the wage-earners. Long periods of unemployment and under-employment have been chiefly instrumental in causing the wage-earners to follow the example of their 'betters'. The authors give facts enough to show that we are now "between two biological worlds: one, the Age of Expanding Numbers, is dead; the other, the Age of Contracting Numbers, is just commencing". We are entering upon an unknown and a perilous period of our history. If, they affirm, the working people of Great Britain had during the past forty years returned the same birth-rate as the well-to-do, we should not have had sufficient man-power to wage the War—and money would not have saved us. Should it be objected that there is an element of guesswork in this statement, there is at any rate none in the next, which relates to the number of children in the school-group 5 to 14. In 1913 the number was upwards of seven millions, in 1938 only six millions. Assuming that the same conditions prevail, Dr. Enid Charles estimates the number as about four millions in 1950, and three millions in 1960. The authors refute in the strongest possible terms the suggestion that the falling birth-rate is due to the selfishness of parents, but their condemnation falls very heavily upon an economic system in which children seem to be simply not wanted. They recite an impressive array of facts to prove their point.

The authors' hope for a future which they aver is not necessarily gloomy lies in getting people to share Abraham Lincoln's belief in a time coming when "Money will cease to be master and become the servant of humanity". They point out that modern sanitation, social services, factory reforms and State education passed muster, not so much because they were right as because they would "pay"; and tha proposals for public works in relief of unemployment were argued only in terms of finance. They gibbet the May Report of 1931 which decided, for example, that Britain could not afford £1½ million a year for extended services to reduce maternal mortality—a sum we now spend in three hours of war.

This book is designed to help the common man to face the fact of revolution in reproduction, for in the long run, as the authors affirm in their final chapter, "The People Must Decide".

SCIENCE IN SOVIET RUSSIA

Science in Soviet Russia

By Seven British Scientists. Edited by Dr. Joseph Needham and Jane Sykes Davies. Pp. v+65. (London: Watts and Co., Ltd.; 1942.) 1*s.* 3*d.* net.

THIS little book provides a most useful glimpse of some of the scientific developments which have contributed towards the prodigious effort of defence by the Soviet Union in the present War.

The strength of science in the U.S.S.R. is based on its position in the official ideology. It is believed that a correct outlook on life and an adequate standard of living involves science as an integral part of all activities, spiritual and temporal. Hence science has been connected with every aspect of life, and its position in the Soviet State might be compared with that of the nervous system in man. As a result of these ideas, immense sums have been spent on laboratories and the training of scientific workers, and developments have been made according to plans. The scientific part of the new social order is in the main only fifteen to twenty years old. It has produced tens of thousands of new young scientific workers, many of them somewhat raw and not yet old enough in tradition to have highly developed scientific intuitions and critical judgments, but superb material for flying and artillery officers and factory management.

The events of the War have driven the chief Allied nations to create scientific organizations which grow more and more similar to the Soviet system of planned science. For this reason, as well as the bare facts, the seven essays in this book are of interest. Dr. Shoenberg's essay on physical research in the Soviet Union is outstanding. He speaks Russian, and has had the opportunity of working in Prof. P. Kapitza's laboratories in both Cambridge and Moscow. His comparative study of the two experiences is most illuminating. He says that the Moscow institute is several times larger, and has pleasant grounds. It has a staff of sixty people, compared with ten in the Mond Laboratory. For each physicist in the Soviet laboratory there are ten other employees, while at Cambridge there is only one. Half of the sixty are janitors, charwomen, chauffeurs, boilermen, gardeners, etc. Ten are office workers, and there was a good deal of 'red tape'. The ratio of mechanics and technicians to physicists was about four times as great as in England. Dr. Shoenberg found this a real boon. They were first-rate craftsmen, and so released much more of the physicist's time for attention to real physical problems.

Another attractive feature is that the research worker belongs to a particularly respected profession, and is not liable, as in pre-war England, to be asked: "But what do you do for a living?"

Dr. Ruhemann writes on industrial research from his six years' experience at Kharkov, Dr. Needham reviews work in biology, Dr. Walton agricultural research, Mr. Roscoe Clarke developments in medicine, and Dr. G. W. Tyrrell the growth of geology and mineralogy.

It is all informative, and is very reasonably priced.

J. G. CROWTHER.

LINEAR DIFFERENTIAL EQUATIONS

Operational Methods in Applied Mathematics

By Prof. H. S. Carslaw and J. C. Jaeger. Pp. xvi+264. (Oxford: Clarendon Press; London: Oxford University Press, 1941.) 17*s.* 6*d.* net.

A WAY to solve linear differential equations by operational methods which avoid the introduction of arbitrary constants by taking direct account of the initial conditions was invented by Oliver Heaviside (1850–1925) for the purpose of discussing electromagnetic waves. In his hands the method led to correct results, but the mathematical foundation was so obscure as to cause it to be regarded with misgiving. Bromwich (1875–1930) was the first to explain Heaviside's method, and, by expressing the solution in the form of a contour integral, to justify its application to ordinary linear equations. Since then many systems, modifications and expositions of varying degrees of merit have appeared.

The present work is based on the application of the Laplace transform

$$\bar{x}(p) = \int_0^\infty e^{-pt} x dt,$$

where p is a positive number sufficiently large to ensure the convergence of the integral and x is a given function of t. Thus, if $x = e^{at}$, $\bar{x}(p) = 1/(p-a)$. To take a very simple illustration, consider the equation $dx/dt + 3x = e^{-2t}$, given that $x = 0$ when $t = 0$. Multiply by e^{-pt} and integrate from 0 to ∞. This gives:

$$\bar{x}(p) = \int_0^\infty e^{-pt} x dt = \frac{1}{p+2} - \frac{1}{p+3},$$

so that $x = e^{-2t} - e^{-3t}$.

It will be seen from the above that the solution is inferred by writing down the function x whose Laplace transform is given, that is, by inverting the transform. In simple cases this can be done by inspecting a list or dictionary of transforms (such a list is given at the end of the book). When inspection fails, the inversion can be effected by a general theorem which expresses x as a contour integral when $\bar{x}(p)$ is given. Thus the method is direct, simple to apply and easy to understand.

The book contains three purely mathematical chapters on the application of the Laplace transform to linear equations with constant coefficients, on the inversion theorem, and on linear partial differential equations. The remaining seven chapters, each complete in itself, discuss a varied and interesting collection of problems in electric circuit theory, dynamics, conduction of heat, vibrations of continuous systems, hydrodynamics, electric transmission lines, electric waves. There are also numerous exercises for the student.

The book is well written, well printed, and can be recommended unreservedly to all who have to make scientific applications of linear differential equations.

L. M. MILNE-THOMSON.

MEASUREMENT OF ELECTRONIC CHARGE

By PROF. T. H. LABY, F.R.S.
University of Melbourne

Oil Drop Method

THE steps in the progress towards precision in the measurement of the electronic charge, e, are well known. The first measurements by J. S. Townsend and J. J. Thomson of 1897 and 1898 were approximate ones. H. A. Wilson in 1903 used a method new in principle, but it was not until Millikan and his many co-workers had completed their comprehensive investigations of the oil drop method and the viscosity of air that e became known with precision.

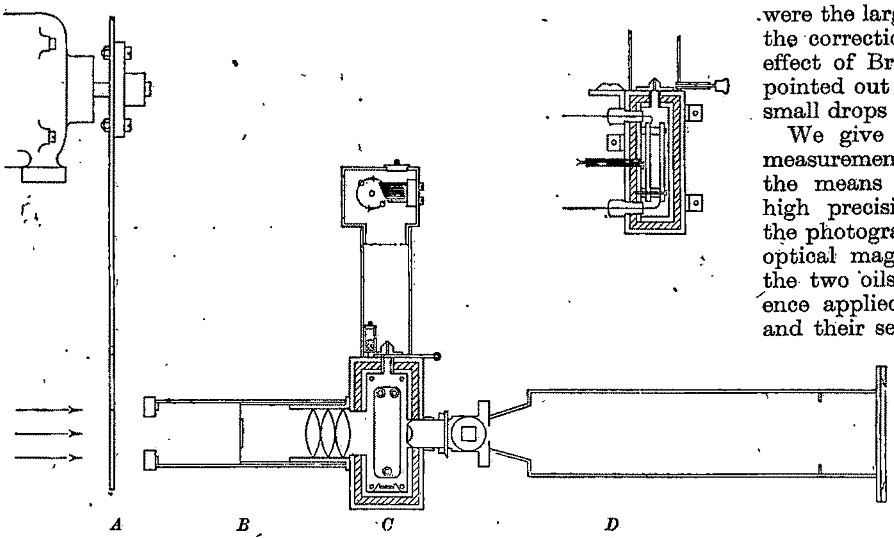

Fig. 1.* SKETCH OF APPARATUS.
A, rotating disk, which allows intermittent entry of light into the optical system.
B, optical system arranged to produce dark-ground illumination.
C, deflecting plates in central chamber arranged vertically so that drops are horizontally deflected by the electric field.
D, camera for photographing image of drops.
Brush for producing oil drops of suitable size is at the top of chamber shown vertically above condenser plates. On the right is a side-view of condenser plates.

*Figs. 1 and 2 are from a paper by V. D. Hopper and T. H. Laby in *Proc. Roy. Soc.*, A, 178.

Millikan's final value was accepted for a number of years without, if not as beyond, criticism until measurements by the X-ray method gave values as high as $4{\cdot}805 \times 10^{-10}$ E.S.U. for the electronic charge; this was greater than his value, $4{\cdot}774 \times 10^{-10}$ E.S.U., by many times the estimated probable errors of both. Some writers then raised the question whether the drop method was comparable in precision with the X-ray one.

There are several other methods of measuring e, as for example the α-ray one, but apparently none of them are precision ones.

Mr. V. D. Hopper and I[1] have determined e by means of a modified oil drop method, similar to H. A. Wilson's, but differing from it in that the electric field acts in a horizontal direction and not vertically. The drop describes vertical and inclined straight line paths.

The expression giving the uncorrected electronic charge, e_1, is

$$Xne_1 = 9\sqrt{2}\pi\eta^{3/2}(\rho-\sigma)^{-\frac{1}{2}} g^{-\frac{1}{2}} v_g^{\frac{1}{2}} v_x,$$

where n is integral, v_g is the free fall and v_x is the velocity of the drop in the direction of the electric field X. The relation

$$e_1^{2/3} = e_0^{2/3} + m/pa$$

corrects e_1 for departure from Stokes's law, where a cm. is the radius of the drop, and p cm. of mercury is the air pressure. The oil drops were photographed (at intervals of 1/25 sec. using a 1/1,500 sec. exposure) to eliminate subjective timing errors, and disturbing effects of the light beam.

Observers	$e_0 \times 10^{10}$	$m \times 10^3$
Authors	$4{\cdot}802\,0 \pm 0{\cdot}001\,3$	$0{\cdot}037\,7_7 \pm 0{\cdot}000\,4$
Millikan	$4{\cdot}799\,2 \pm 0{\cdot}003\,7$	$0{\cdot}037\,8_4 \pm 0{\cdot}000\,1$
Bäcklin and Flemberg	$4{\cdot}781\,1 \pm 0{\cdot}018$	$0{\cdot}037\,2 \pm 0{\cdot}001\,4$
Ishida *et al.*	$4{\cdot}835\,0$	$0{\cdot}036\,1$

We used large drops (eight of them were the largest so far used) to decrease the correction to Stokes's law, and the effect of Brownian motion. As Perrin pointed out many years ago, the use of small drops invalidates the method.

We give full details of the actual measurement made in our paper, and the means adopted to measure with high precision the distances between the photographic images of a drop, the optical magnification, the densities of the two oils used, the potential difference applied to the condenser plates and their separation. The values of e_0 and m with their errors are given in the table above.

The probable errors are calculated from internal consistency by means of a least square formula quoted by Birge in one of his valuable discussions of least square theory. It is evident that the oil drop methods used by us and by Millikan give values for e and m in close agreement.

In calculating e we have used in the table above $\eta_{23} = 1{\cdot}83006 \times 10^{-4}$. Since η enters as $\eta^{3/2}$ in the expression for e, the value assumed for η as being the most probable is very important. We have critically examined nine recent measurements of η for air and derived a mean value. The error of the mean, $\pm 0{\cdot}0025 \times 10^{-4}$, is several times larger than the error of the more accurate of these values as estimated by internal consistency. There is this and other evidence that measurements of the viscosity of gases are subject to large systematic errors. The error in η mentioned contributes an error of 1 in 500 to e, and is now its main error by the drop method.

X-ray Method

In the X-ray method the lattice spacing, d cm., of a crystal is measured, and $e = 2d^3\,\phi(\beta)\,\rho F/M$, where $d^3\,\phi(\beta)\,\rho$ is the mass of the crystal molecule, M its molecular weight, and F the Faraday. This is done in several steps. First the wave-length, λ_g cm., of an X-ray line is measured. For example, the K doublet of aluminium was measured absolutely by Bäcklin using ruled gratings, and Söderman and Tyrén[2], using concave gratings, compared the aluminium line in

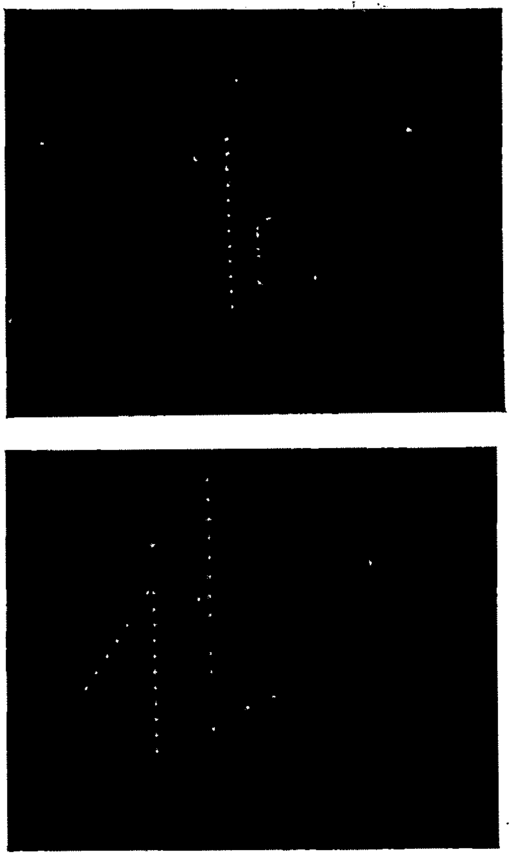

FIG. 2. PHOTOGRAPHS SHOWING PATHS OF DROPS BEFORE AND AFTER THE APPLICATION OF THE ELECTRIC FIELD.

Time interval between the appearance of consecutive images is 0·04 sec. Time of exposure for each image 0·0007 sec. Magnification of camera, × 12.

high orders with optical lines of the spark spectra of carbon, oxygen, etc., the wave-lengths of which Edlén had measured.

Next the wave-length of the X-ray line, λ_c x.u., is measured using an X-ray spectrometer and a crystal. Since for calcite λ_c Al $K\alpha_{12}$ is greater than $2d$, it cannot be used as the crystal. Mica, gypsum, and quartz crystals have been used. The lattice constant of the crystal used is compared with that of calcite using copper $K\alpha_1$ or other homogeneous radiation. The observations of Larsson, Siegbahn and Haglund agree closely, giving λ_c Al $K\alpha_{12} = 8322{\cdot}90$, where, as defined by Siegbahn (and always used by him), 1 x.u. = d_{18} calcite/3029·45.

The expression $e = (\lambda_g/\lambda_c)^3\ 4{\cdot}77302 \times 10^{-10}$ is used to calculate e; it is calculated using the most probable values of ρ, $\phi(\beta)$, F and M.

X-RAY VALUES OF *e*

Bäcklin	$4{\cdot}8017 \times 10^{-10}$	Tyrén	4·8020
Söderman	$4{\cdot}8027 \times 10^{-10}$	Bearden (1935)	4·8029

Mean X-ray value $(4{\cdot}8023 \pm 0{\cdot}001)\ 10^{-10}$ E.S.U.

If $\eta_{23} = 1{\cdot}8301 \times 10^{-4}$, the values of e are: Millikan, 4·799; Hopper and Laby, 4·8020; X-ray value, $4{\cdot}8023 \times 10^{-10}$ E.S.U., and the two methods agree.

Hopper, V. D., and Laby, T. H., *Proc. Roy. Soc.*, A, **178**, 243 (1941).

GEOLOGY IN CHINA

ANNIVERSARY OF THE GEOLOGICAL SOCIETY OF CHINA

TO say that the activities of Chinese geologists during the past few decades have been remarkable seems almost an understatement: our admiration of their achievements is quickened by the reflection that the Geological Society of China was founded only twenty years ago. Even under the handicap of present conditions, the Society recently celebrated its twentieth anniversary, when Dr. J. S. Lee, as chairman, delivered an inspiring address. We in Great Britain feel gratified when we remember that Dr. Lee is one of the many Chinese geologists trained in a British university (in this case, Birmingham), and we look forward to a resumption and even an extension of this practice after the War. By this means we make close scientific contacts (which benefit those who give no less than those who take) with a country vast in area, varied in physical features and diversified in rock-types.

In China we see a part of the earth's crust where geological processes have been developed on the grand scale. Although geological history cannot actually repeat itself anywhere, we can usually detect recurrent phases that show mimetic resemblances. Moreover, it would seem that although the principles of geological science are by their very nature applicable to all terrestrial areas, each major unit of the continental surface displays its own peculiar features. For example, the surprising geological discoveries made year by year in Africa remind us that, so early as Pliny's time, men were accustomed to look to Africa for things always new. Since then, North America, India and the U.S.S.R. have produced their crops of geological novelties; and now we can appropriately apply to China the well-worn aphorism. Even the popular imagination is stirred by such events as the unearthing of fossil dinosaur eggs or the skull of Peking man, but these discoveries are matched by no less remarkable, if more esoteric, discoveries in the fields of mineralogy, palæontology, stratigraphy and tectonics.

The two decades that have elapsed since the foundation of the Geological Society of China have seen great political upheavals in the country, the setbacks due to ideological rivalries and a bitter war of penetration arising out of the economic ambitions of a neighbouring power. Such conditions are certainly not favourable for the prosecution of scientific work, and we cannot but marvel at the way in which our Chinese colleagues have succeeded in carrying on both laboratory research and the primary survey of the rocks of their motherland in spite of manifold difficulties, of which transportation is not the least considerable.

Dr. Lee's review of progress in Chinese geology during the past twenty years is a timely reminder of what can be accomplished in adverse circumstances by devotion to science: it is also a stocktaking which serves to indicate those fields in which more knowledge is urgently needed. At the outset, he directed attention to the "extraordinary fact" (to quote his own words) ". . . how few is the number of papers dealing with the economic aspect of geology that appeared in the bulletin of this society. Among the reasons to account for this record, I would point out one: namely, that a non-utilitarian tendency has always constituted a strong trait in the character of Chinese intelligenzia throughout historical times".

The misuse of scientific discoveries and the perverted developments elsewhere lead him to the reflection that (as he puts it) handicaps such as those due to the absence in a country of any legacy of geological ideas sometimes turn out to be an advantage. The contrast in outlook is emphasized by the action of the covetous neighbour who has invaded China in order to exploit the natural resources, especially of minerals. Comparatively little is known about the potentialities of the huge area of China which, *sensu lato*, covers more than one tenth of the earth's land surface: their proper assessment will inevitably call for a large army of investigators, and the information thus acquired will materially affect any action taken to implement the Fourth Article of the Atlantic Charter.

Dr. Lee notes that the Geological Society of China, although a national organization, is in fact international in character, as witnessed by the roll of members, who come from all lands. Many have participated in the work of the Society and are welcomed in a fraternal atmosphere. As he pointedly says, "we have even adopted the leading Western languages, principally English, as the official means of communication, not without some sacrifice of our own convenience". For this, as also for the fact that he gave his address in English, we are very thankful.

Some of Dr. Lee's animadversions are in the nature of warnings to his geological colleagues not to rely too much on the range of fossils and on stratigraphical divisions established in other parts of the world. He cites as examples the discovery of the tabulate coral Tetrapora, formerly believed to be typically Permian, in beds so ancient as the Lower Carboniferous; of a species of Sphenophyllum hitherto unknown below the Stephanian coal measures of Europe, in the Wuntung Sandstone of Lower Carboniferous age; and of the Upper Devonian fish Bothriolepis in the lower part of the Middle Devonian. He mentions other instances in order to show that the stratigraphical value and zonal positions of fossils in China are not in conformity with records established elsewhere. There are considerable lacunæ, he says, in the fields of mineralogy and petrology, such as the study of the constituents of the sedimentary deposits and the natural history of the igneous and metamorphic rocks of China. Both merit further attention, and his country offers generous scope for these lines of inquiry.

The survey of complex petrological provinces has necessarily proceeded slowly and map-making has been delayed, a fact which reminds Dr. Lee to mention incidentally the appearance of a gorgeously coloured geological map of Southern China, published by a foreign institution (and we can make a shrewd guess at its source, knowing which nation specialized in such regional activities) at a time when even the larger units of the stratigraphy were scarcely known! But, as he says, the absence of authoritative geological maps of China invites such "indignities".

After dealing with the subject of mapping, Dr. Lee is led to a discussion of problems of palæogeography, and he takes the opportunity to warn his colleagues against the danger of inferring the onset of important earth-movements from evidence which denotes non-sequence rather than major unconformity. As a prelude to the discussion of geophysical phenomena and tectonics, he describes examples of rock deformations that may astonish Western workers, such as the yielding of tombstones under their own weight and of the bending of pebbles of chert and hard sandstone under a load of ice only 100 m. in thickness.

Dr. Lee's early attempts to classify the structural features and mountain forms of China are well known to us, for they found publicity in an English geological journal. In his view, these features fall into three dominant groups, the Cathaysian and Neo-Cathaysian trends (the former dating from the Palæozoic and generally running north-eastwards, and the latter probably late Mesozoic and running north-north-eastwards), the east-west fold-zones, and the various shear-forms. The dominant shear-forms, five or six in number, are of his epsilon-type and each extends over the whole or part of a segment of the continent and is separated from the other by fold zones, their arcuate convex fronts facing the equator. Dr. Lee sees this structure also in the sweep of the Eurasian arcs, combined with the backbone of the Urals, and suggests that a similar arrangement can be found in North America. From experimental results in the laboratory, he infers that these features are characteristic of the behaviour of a plasto-elastic material when subjected to stresses, and that in the earth's crust they result from "the horizontal component of the centrifugal force arising from the spin of the earth, or more probably from an increase of its rotational speed". Dr. Lee admits that his generalizations are likely to arouse scepticism in some quarters. He makes reference also to a rather better known effect of the earth's rotation when he records that, like the meridionally flowing rivers of Russia, the mighty Yangtze is at the present time undercutting steeply its right-hand bank after it leaves the gorges

Dr. Lee concludes his address with a summary of the evidence for a polyphase Ice Age in China, in which there were not less than three separate glacial episodes. Incidentally, he correlates one with the "Würm of Europe": now, the Würm episode in the Alps is generally known, but opinions differ widely about the particular phenomena that distinguish its traces elsewhere.

Although only a few of its many interesting points can be mentioned here, we may take this opportunity to hail the address as contributory evidence of the virility of young China.

P. G. H. Boswell.

ELECTRON LENSES[*]

By Dr. D. GABOR

Research Laboratory of The British Thomson Houston Co. Ltd., Rugby

As soon as H. Busch had established the analogy between axially symmetrical electromagnetic fields and optical lenses, a question very naturally suggested itself: "Can we make electron lenses as perfect as the highly corrected lenses of modern optics?"

Compared with light optics the new science started with a great advantage, and with a great disadvantage. Whereas in optical instruments the ratio of refractive indexes never exceeds 2 : 1, in electronic devices we can realize ratios of 1000 : 1 or more, by using sufficiently high accelerating voltages. Against this stood the great disadvantage that while modern applied optics has a great variety of glasses at its disposal, with a wide range of chromatic dispersivities, electron optics has only two media, the electric and the magnetic fields, both with fixed properties. Nor can we shape the electron lenses as freely as the optician figures his surfaces, as we are limited by the conditions of zero divergence for the electric field, and zero curl for the magnetic field (freedom from space charges and space currents).

---

[*] Substance of part of a lecture on "Electron Optics" before the Electronics Group of the Institute of Physics delivered on October 3. The complete lecture is being published in *Electronic Engineering*.

It will be useful to sum up in advance the position as it is now, after fifteen years of theoretical and experimental research. It was *not* possible in theoretical electron optics to design perfect or at least highly corrected lenses of high power. The initial disadvantage proved too great. On the other hand, the electron optical art could solve all its immediate problems by availing itself of the great inherent advantages of electron optics, by the use of *high voltages*. Almost the only service theory could render was to point out the unavoidable limitations, thus saving the workers from wasting time and energy on *perpetuum mobili*.

The first question which arose was: "Can an electron lens form a point image of a point on its axis?" Two defects are possible, due to spherical and 'chromatic' aberration. O. Scherzer demonstrated in an important paper[1] that neither can be eliminated. These two fundamental weaknesses of electron optics are closely connected with the impossibility of realizing diverging electron lenses under the conditions required by present-day practice, namely, zero space charge, and zero electric field both in the object and in the image space. In principle, the spherical aberration could be corrected by suitably controlled auxiliary streams of ions or electrons. But so far, experimenters have not been tempted to follow this line, which is bristling with difficulties. It may be asked whether the space charge of the electrons themselves which forms the image could not be used for this purpose? In fact, a perfectly stigmatic beam carrying a finite current density is not in principle impossible*, as the electrostatic energy stored in it is finite. It may even be surmised that this method of compensation has been unwittingly but successfully utilized in many cathode ray tubes. But it is useless in electron microscopes. A hint regarding these came from R. Rebsch[2]. Though the spherical aberration can never be quite eliminated, it can be reduced below any limit, if the field of the objective is so shaped that it forms a very small, very weak 'prefix lens' extremely close to the object. But to realize this requires extreme mechanical precision, and there is no evidence that practice had availed itself of Rebsch's suggestion.

When it was discovered in 1936[3] that *electron mirrors* had chromatic errors of opposite sign to those of lenses, it seemed that there was hope of correcting for chromatic aberration. But this was a forlorn hope, for several reasons. In mirrors, the image field will cut out the paraxial rays, and correction to a very high order becomes necessary, or the mirror has to be placed in a skew position to the axis, and all the formidable difficulties of non-centred optical systems have to be faced, which even in light optics have only partially and recently been overcome. But apart from these theoretical difficulties, electron mirrors offend badly against what I should like to call the first principle of *practical* electron optics: 'Do not slow down your electrons more than you can help".

I do not know whether this principle has ever been formulated, but the whole development of the electron optical art proves that it has been understood and observed. In fact, it is a very common experience in electron optics that electrostatic systems show performances far below theoretical expectations, and display defects far worse than could be accounted for by the geometrical inaccuracy of the electrode arrangement. The reason is that the electrode surfaces are often covered with what may be called somewhat vaguely *polarization layers*, which are often distributed in a patchy, irregular way, and can produce, between the surface and the body of the electrode, potential differences of several volts, sometimes even more than a hundred volts. So far as I know, they have never been systematically studied. Indeed, they present a rather typical case of a problem which is likely to be neglected. Academic circles cannot be expected to be interested in them, as they are far off the main road of progress. Industrial physicists have no time for this sort of problem; they will remove the difficulty by some *ad hoc* solution, or pass in a wide circle around it. But until the polarization layers are eliminated, all electrostatic systems using slow electrons are likely to be disappointing, and this is particularly true of electron mirrors.

Though, as we have seen, theory was not very helpful, electron optical practice has achieved brilliant successes. I have already mentioned the simple panacea of practice: *high voltage*. No high-power lenses were possible, but there was no need for them, because with sufficiently high voltages very much greater intensities† could be realized with electrons than with light. Moreover, the de Broglie wave-length of high-velocity electrons is very much shorter than the wave-length of visible light, so that, for example, at 60,000 volts the numerical aperture of an electron microscope could be cut down to 1/1000, and yet a hundred times higher resolving power could be realized than with a light microscope of unit numerical aperture.

With such narrow apertures even the aberrations of entirely uncorrected lenses become negligible, with the exception of the chromatic aberration. For this, however, practice had the simple remedy of monochromatic illumination, the electron optical translation of which is *constant voltage*. In the new commercial electron microscope of the RCA[4], the supply of 60,000 volts is kept constant within ± 1·2 volts, that is, 0·004 per cent, which means that the de Broglie wave-length of the electrons varies only by 0·002 per cent. In comparison, a sodium lamp is a very poor monochromatic source, as the two *D*-lines differ by 0·1 per cent, which is fifty times more. This almost perfect monochromatism is somewhat disturbed by the scattering in the specimen. But here again high voltage proves its claim as a panacea. The faster the electron, the less energy will it lose in a single collision, and if the specimen is sufficiently thin, the inhomogeneity of a 60-kv. beam emerging from it will be almost negligible, while the scattering (change of direction without appreciable difference in energy) is still sufficient to provide good photographic contrasts. Thicker specimens have been successfully investigated with 300-kv. electrons[5].

To sum up, practice has not waited for highly corrected lenses, but short-circuited the problem by pinhole apertures and monochromatic illumination. It appears even that further progress at the moment is not barred by lens imperfections, but by the polarization layers which form especially in the objective aperture[6]. This is one more reason for taking up their study in earnest.

---

* Strictly speaking, not *optically* impossible. For thermodynamic reasons a rigorously stigmatic beam can never be realized.

† Intensity is energy flux per unit area and per unit solid angle.

Years ago, when highly corrected lenses appeared more important than at the present time, I often thought that it would be desirable to know the fields corresponding to *ideally stigmatic lenses*, regardless of the difficulty of their realization by current laboratory methods. After labouring on the problem without success for some time, I dismissed it from my mind, but recently when I again gave attention to the subject I found a very simple way leading to the solution. Though the result itself may not be of practical importance at the present stage of electron optics, I think that the method by which it is derived may be of interest.

Hamilton's Principle can be expressed in a form identical with Fermat's Principle

$$\int n.ds = \text{minimum},$$

where ds is an element of the trajectory and n is the electron optical refractive index. Let us apply this to the trajectories in the meridian plane of a lens. In this case n is independent of the direction, not only in electrostatic lenses, but also in the magnetic type, if we allow for the rotation of the trajectory around the axis.

Let us now map the meridian plane of the lens on a suitably chosen surface by a transformation

$$n.ds = dS,$$

where dS is the line element on the surface corresponding to ds. As n is isotropic, the transformation is *isomorphic*. A surface on which the meridian plane of the lens can be mapped in this way may be called a geodetic surface, as every electron trajectory will be mapped on it as a geodetic line[7].

This leads straight to the 'ideal lens', as it is obvious that *the geodetic surface of an ideal lens must be a sphere*. On a sphere the geodetics are great circles, and the great circles running through *any* point intersect again in its antipole, which can be considered as the rigorous image of the point considered. We can now map the sphere on a plane by *any* isomorphic projection known in cartography, and obtain an *ideal two-dimensional lens*. In order to obtain the ideal three-dimensional lens we choose the stereographic projection, on account of its central symmetry. This gives the following law for the distribution of the refractive index as a function of the radius vector r in the meridian plane:

$$n/n_0 = (1 + r^2/r_0{}^2)^{-1},$$

where n_0 is the refractive index at the centre, and r_0 a length which characterizes the dimensions of the lens. If we imagine this distribution rotated round any axis, we obtain the ideal three-dimensional lens. Because of its spherical symmetry, any trajectory will be contained in a meridian plane. The trajectories are one and all *ellipses*. An image of any point at a distance r_1 from the centre will be formed rigorously at a point on the same diameter at a distance r_2, and the simple relation between the two is

$$r_1.r_2 = r_0{}^2.$$

Image formation is therefore the geometrical transformation known as *inversion*. It can be proved that the three-dimensional ideal lens is unique. If there were other ideal lenses, they could be derived from the one described by isomorphic transformations. But according to a theorem of Liouville the group of isomorphic transformations in three dimensions is identical with the group of inversions, and according to a theorem of Cayley and Klein the group of inversions represents, by stereographic transformations, the rotations of a sphere on itself. As rotations of the geodetic sphere on itself are irrelevant, the ideal lens is transformed into itself, and is therefore unique.

Though it may be satisfactory to know that the ideal lens exists in the mathematical sense of 'existence', no immediate practical application can be expected, as it cannot be realized without space charges. The same is true of the infinite number of two-dimensional (cylindrical) ideal lenses, though some of these may be capable of approximate realization. These are all derivable from the 'stereographic' distribution by any conformal representation in which the action is kept invariant:

$$n.ds = n'.ds'.$$

It may be hoped that such representations will have other, less ambitious but more immediately fruitful applications, as they allow the transformation of one electron optical problem into another, and may even hold the key to certain space-charge problems, for which no satisfactory mathematical treatment has yet been found.

HEALTH EDUCATION IN GREAT BRITAIN

MANY of the most important institutions in Great Britain have, like Topsy, 'just growed', and among them is the Central Council for Health Education. Set up originally in 1927 as an offshoot of the Society of Medical Officers of Health, it has grown until it is now recognized by the Government as "the one agency for general health education in England and Wales", with thirty-nine members on staff and fifty-four active recognized lecturers. Since the Council, at the instigation of the Ministry of Health, took over in April of this year the major part of the work previously carried out by the British Social Hygiene Council, together with most of the staff responsible for it, its activities have increased enormously. The Council has regional offices in various parts of the country, which facilitates work considerably, and encourages local initiative.

The general public is probably most familiar with the Council's poster advertisement—indeed "Coughs and Sneezes spread Diseases" has become a nationa slogan. Posters are available for the use of loca authorities in sufficient diversity to cover most con ceivable needs. The disease-spreading proclivities of the rat and the fly; the life-histories of the bug the louse and the scabies mite; the importance of diphtheria immunization and whooping-cough inocu lation; the desirability of rambling, cycling and camping; the benefits to be derived from breast feeding and attendance at infant welfare clinics—

all these and many other health lessons may now be brought to the attention of the public by display on the hoardings. Local authorities are not slow to appreciate the advantage of this centralized poster production, as evidenced by the fact that in the first six months of this financial year, the Central Council has disposed of some twenty-three thousand posters and bills.

Apart from posters, the main medium of printed propaganda is the leaflet. Most of the Central Council's leaflets fall into several attractive series such as "Health Hints", "Hints from the Health Department" and "Shelter Bulletins". These cover a wide field of health education, ranging from brief outlines of diseases such as diphtheria, measles, whooping cough, infantile paralysis, tuberculosis and influenza, to the importance of bodily and sartorial cleanliness, sleep and the adequate feeding of baby, toddler and expectant mother. In addition, several pamphlets are available; while those leaflets and pamphlets dealing with the biological approach to sex education and the problems of venereal diseases (taken over from the British Social Hygiene Council) are, after suitable revision, being re-published in similar format. The scope of this type of publicity may be estimated by the fact that in six months some 885,000 leaflets and pamphlets have been distributed by the Central Council. Not content with this range, the Council is actively engaged on the preparation of new pamphlets dealing with the health of school-children (from the points of view both of the teacher and of the parent), with the problems of adolescence (for youth leaders), with the health of factory workers, and with biology as a medium of health education in the school; and of new leaflets concerning the health of the worker, the care of the feet, advice to dyspeptics, and other topics. In addition, an illustrated health booklet for children will soon be available.

A central health education agency could scarcely regard its work as satisfactory in the absence of a periodical, and the Central Council is in the fortunate position of having two. *Better Health*, a small popular monthly, achieves a circulation of 50–60,000, and, when paper limitations are removed after the War, should reach many times this figure. In addition to a popular magazine for the general public there has, however, been for many years a real need for a journal of a more specialist nature, to cater for those many people actively working in the field of health education. This need should be met by the publication, in January of 1943, of the first number of a new quarterly, *Health Education*. Articles by specialists will help to give educationists more information on medical matters, and medical people more on matters of education.

The first number will contain a message from the Minister of Health. Dr. Allen Daley (chief medical officer of the London County Council) will contribute an article describing the beginnings of health education in Great Britain, while Prof. J. M. Mackintosh will give his views of the primary aims in health education, and Dr. Charles Hill (chairman of the Central Council) will consider radio as a medium of health education. Mr. W. B. Little will discuss health education from the point of view of the school-teacher, and Dr. J. L. Picton from that of the general practitioner, while the problems of sex education will be considered by Mr. Cyril Bibby (education officer of the Central Council). This new journal should prove of the greatest value to medical practitioners, teachers, youth leaders, social workers, medical and educational administrators and indeed to all seriously interested in the matter of health education.

No educational body to-day can afford to neglect the medium of the film, and the Central Council has not been backward in this respect. It now has available for the use of local authorities some fifty films, covering the most varied aspects of health education. Droplet infection, nutrition, the care of the skin and of the feet, the conquering of fear, the historical development of the public health services, the biological approach to the study of sex and reproduction, the venereal diseases—all these are dealt with in the Council's films, in manners suitable for the most diverse audiences, from school-children and the general public to educationists and medical practitioners. Not content with this range of subjects the Council has at present in production new films on the head louse, venereal diseases, infant welfare clinics, and a film fantasy for children, showing the importance of cleanliness, exercise, fresh air, and good food.

During the last six months the Council's films have been shown at some four hundred special meetings. In addition, more than three hundred health films have been dispatched to a hundred borrowers. To meet this demand for visual health education the Central Council employs seven film operators, and possesses ten film and six film-strip projectors.

The radio is also a medium of the utmost importance, and it has not been neglected. In collaboration with the Central Council for School Broadcasting, the chairman of the Central Council for Health Education has given many health talks to school-children; and millions must hear him as the "Radio Doctor" in the B.B.C. programmes.

Important as all these methods of health education undoubtedly are, perhaps most potent of all is the spoken word of a lecturer to his audience. With the helpful co-operation of local authorities and the various national voluntary organizations, the Central Council arranges large numbers of meetings for many different types of audience, and more often than not the meetings are illustrated by films. During the six months from April 1 of this year more than 75,000 people have been reached in this way.

This number is but a small part of the total population of Great Britain, but many audiences are highly selected, consisting of influential persons, who will pass on the knowledge obtained to, or will be influenced in their dealings with, many others. This is particularly true of the meetings for school-teachers, who have such a great influence over children and young people. Thus it is reasonable to expect that the 762 teachers who have during these six months attended lectures at eleven different centres in the country will, as the years go by, affect favourably tens of thousands of the future citizens of the country. These teachers' refresher courses have dealt with the biological approach to problems of sex and of health generally, and have been fairly thorough courses of up to twelve sessions. The Central Council has built up a comprehensive display library of biology and hygiene books, and teachers have been very grateful for the opportunity of examining it at the meetings.

Similar significance beyond the mere figures of attendance applies to the 1,566 youth leaders and welfare supervisors who have in the same period attended courses dealing with the problems of adolescence; and to the 1,111 parents who have taken part in meetings dealing with the sex and health education of children.

An important feature of the work of the Central Council is the talks on sex and general health problems given directly to school-children and young people. No fewer than 1,466 of the former and 4,596 of the latter have attended courses of lectures given in this half-year in sixty different parts of the country, and all the signs are that the figures for the next half-year will be even greater.

During the period under consideration, approximately three thousand civil defence workers and seven thousand troops have attended meetings organized by the Central Council for Health Education, while factory meetings have reached some thirty-nine thousand workers.

Work of this variety and of this extent is possible only by the collaboration of skilled personnel and influential national organizations. Under its president the Archbishop of Canterbury, the Central Council meets as a widely representative body. Of Government departments, the Ministry of Health, the Board of Education, the Ministries of Food, Labour and Information, the Welsh Board of Health and the Scottish Education Department all have either representatives or observers on the Council or its Committees. In addition, there are representatives from the County Councils Association, the London County Council, the Association of Municipal Corporations, the Non-County Boroughs Association, the Metropolitan Boroughs Standing Joint Committee, and the Urban and Rural District Councils Associations.

The collaboration of the professions most concerned with health education is assured by representation from the Society of Medical Officers of Health, the British Medical Association, the Royal College of Nursing, the Dental Board of the United Kingdom, the British Dental Association, the Association of Directors and Secretaries for Education, the Association of Education Committees, and the National Union of Teachers. The field of health insurance is covered by representatives of the National Association of Insurance Committees, the Association of Welsh Insurance Committees and the London Insurance Committee, while collaboration with other health organizations is achieved by representation from the Conference of Affiliated Societies. In addition, the Council's Educational Advisory Committee has the benefit of the knowledge and experience of representatives from the British Medical Association, the Association of Women Science Teachers and the Science Masters' Association, and of many distinguished educationists (see also NATURE of November 7, p. 529).

Thus for the first time Great Britain has a really large and representative organization with skilled personnel devoted entirely to the enormously important work of health education; and the country should benefit greatly from it.

NEWTON TERCENTENARY

ROYAL SOCIETY CELEBRATIONS

THE anniversary meeting of the Royal Society, which is held on Saint Andrew's Day, November 30, was this year devoted, for the most part, to commemorating the tercentenary of the birth of Isaac Newton. The proceedings, which took place in the lecture theatre of the Royal Institution, were opened by Sir Henry Dale, president of the Royal Society, and the main part of his address is printed below.

We are within a few weeks of the three hundredth anniversary of the birth of Isaac Newton. Wherever the progress of our Western science and philosophy has become effective, men will remember what that event was to mean for the world. Newton, at the age of forty-three, when he had determined to abandon all further concern with natural philosophy, was induced at length, by Halley's friendly insistence, to give written form and system to the mathematical discoveries with which his amazing mind had been occupied over a period of some twenty years. The result was one of the greatest intellectual achievements in the history of mankind—the "Principia", providing for more than two centuries a framework for the mechanical interpretation of the universe and a basis for the building of physical science, and therewith of the material structure of our modern civilization.

We in Britain regard Isaac Newton as still, beyond challenge, the greatest of our men of science. Nor should the claim be limited to this island or to the British Commonwealth of Nations; for it was not until nearly half a century after Newton's death that former British colonists in North America began their development of an independent nation; and Newton is theirs as well as ours.

But, while we may proudly claim him as the countryman of all who share the birthright of the English tongue, the discoveries of science have belonged, and must belong again, to the whole world, and Newton's achievement is a part of the common heritage of all peoples. It cannot be doubted that, if it had fallen in normal times, this tercentenary would have been marked by the greatest of international gatherings, in which men of science and philosophers from all the world would have assembled to do honour to Newton's memory. It would have been natural then to expect leadership, in such an enterprise, from the only two institutions which were intimately concerned with Newton's career as a man of science—Trinity College, in Cambridge, and this our Royal Society of London. Our two foundations did, indeed, confer as to the wisdom of attempting by joint action, even in this year of war, to arrange such a restricted and domestic celebration as the present conditions would allow. We agreed, however, to put aside such planning for the present, carrying it forward in our hopes to the time when a world at peace may be able to join in international commemoration of an event which has meant so much for all mankind. May the time be not too far distant.

In the hamlet of Woolsthorpe, near Colsterworth on the Great North Road, some six miles south of Grantham, there is still a modest manor farm-house, with a small orchard in front of it. Here the Newtons lived, simple yeoman farmers, and here, two months after his father had died, Isaac Newton was born, a puny, premature infant, on Christmas day 1642, twenty years before the Royal Society was incorporated by the grant of its first Charter. The house stands but little altered since that day. The room in which Newton was born has a simple marble tablet on the wall, inscribed with Pope's well-known couplet. But this house had importance in Newton's later life and in his work, and not only as his birthplace. It was here that he returned from his schooling at Grantham, at the age of sixteen, to take charge of the farm for his mother; and here, to the incalculable gain of science and the world, he showed such incompetence as a farmer that he was sent back to school, and thence to Cambridge. It was here, again, that he returned in the autumn of 1665, when the plague drove him from Cambridge; and here, during the following eighteen months of quiet exile in the country, his early ripening genius grasped already the essential principles of his major theoretical discoveries. You can still see the upper chamber which he then used as a study; and in the little orchard there is an old, recumbent apple tree, which, they will tell you, is descended by direct grafting from that which Newton saw. The land which Newton's family farmed is rapidly being laid waste, alas, by quarrying for ironstone; and soon there will be little left unspoiled save the orchard and garden around the house.

It has seemed to us that, in this year of commemoration, something should be done to preserve for posterity a house and garden which carry such momentous memories, and which have meant so much for science. We have accordingly formed a small committee, in which Sir John Russell and Sir James Jeans have joined with the officers of the Royal Society; and we are in negotiation with the lord of the manor as to the possibility of acquiring this now tiny but historic property, so that it may be put for as long as possible beyond the risk of damage or decay.

Then I think that it is our special duty at this anniversary meeting to remember that, while Newton's great discoveries belong to the world, they came to publication through the Royal Society, and that Newton occupied its presidential chair for the last twenty-four years of his long life. Though his "Opticks" was not published until after he had become president, his original work for science was practically finished by the time of his election, and he had for some years been Master of the Mint. There can be no doubt, however, that the wide fame of his achievements, and the respect and admiration in which he was everywhere held, did much, at a critical period in its history, to establish the prestige of this Society in the eyes of the world. Let us then remember to-day that Isaac Newton, the greatest man of science of our race, was also the greatest of the Royal Society's presidents.

Sir Henry Dale also referred in appreciative terms to the attitude of the present owner of the Newton house and garden at Woolsthorpe, Major Christopher Turnor, who had expressed his willingness to dispose of the property for less than its value, for preservation as a Newton memorial. Sir Henry added that he had just learned that the Pilgrim Trustees would defray the cost of purchase. A photograph of the house was reproduced in NATURE of March 26, 1927 (Supp. p. 34), on the occasion of the two hundredth anniversary of Newton's death.

Sir Henry Dale's address was followed by lectures by Prof. E. N. da C. Andrade on "Newton and the Science of his Age", Lord Rayleigh on "Newton as an Experimenter" and Sir James Jeans on "Newton and the Science of Today". The manuscript of the first edition of the "Principia", the reflecting telescope and a solar sundial made by Newton, and other Newtoniana were exhibited in the library of the Royal Institution, together with demonstrations arranged by Lord Rayleigh to supplement those which accompanied his lecture.

OBITUARIES

Prof. J. N. Collie, F.R.S.

BY the death on November 1 of John Norman Collie, chemistry has lost one of her most outstanding personalities. To me, who knew him well from January 1889 until September 1939 when he left London to live in Skye, Collie was a true guide, philosopher and friend, and to-day it is my privilege to write of him as one of his last remaining friends for fifty-three years.

Collie was born on September 10, 1859, and was the son of the late John Collie. He studied chemistry under Prof. Letts at Bristol and afterwards was associated with Letts in two original investigations, the first on dimethylthetine ethyl ester and the second on tribenzylphosphine and tetrabenzylphosphonium salts.

In September 1888 Collie was appointed by Prof. W. Ramsay demonstrator in the Chemical Laboratories in University College, London, and I first met him when I entered the College as a young student in January 1889. Those of us who learned qualitative analysis under Collie found in him a born teacher, gifted with a salutary sarcasm which was tempered with a real understanding of the difficulties presented by a hitherto unknown field of study and provoked by strange results unrecorded in any text-book.

In 1896 Collie left University College on his appointment to the chair of chemistry in the College of the Pharmaceutical Society in Bloomsbury Square, London. In 1902 Collie returned to University College as professor of organic chemistry under Sir William Ramsay, the director of the Chemical Laboratories.

In the years following this appointment, Collie built up a great school of organic chemistry, and many men of high distinction to-day received their inspiration from him. Amongst these may be mentioned Prof. S. Smiles, Prof. T. P. Hilditch, Prof. A. W. Stewart and Dr. Irvine Masson. Just as on a ship the master is called the "Old Man", so it was in the organic laboratory, for Collie was invariably referred to as the "Old Man", a title of which he was very proud, for he knew all that in it lay—unbounded respect, admiration and affection.

Since my contacts with Collie in those years were mainly outside organic chemistry, it is more fitting that another should pay tribute to him as one of the great organic chemists of his time. Prof. Smiles writes: "I hesitate to compare Collie and Perkin, they were so different and yet supreme in their own line in their day. If I must compare them, I would attempt an analogy, a poor one as all such must be. Collie I would regard as the landscape gardener, whilst Perkin was the energetic producer of really fine crops of new varieties. Collie took a very broad view of the subject, the relations of various parts of it to one another, and of the whole to other branches of chemistry. He was no specialist, anything which savoured of narrowness was repugnant to his nature, but he was a true philosopher. It was this that made his lectures and his teaching so interesting, for there always seemed to be something intriguing beyond the horizon of what he was saying. Collie always seemed to publish reluctantly, but anything he did publish was nearly always of a fundamental character; for example, dimethylpyrone and the related compounds which led to his really comprehensive generalization on the polyketides. Collie was the first to suggest a labile formula for benzene, which was familiarly known in the laboratory as the 'Collywobble'. Moreover, his investigation of naturally occurring compounds, necessarily in small quantities, led him to devise his semi-micro method of organic analysis long before the days of Pregl."

In 1913, when Ramsay retired, Collie was appointed director of the Chemical Laboratories at University College, a position he held until his retirement as emeritus professor in 1928.

Now Collie was endowed with a remarkable versatility. In my days as a young student, he gave me what he called the education of a gentleman. At a series of dinners in his rooms in Camden Grove, he discoursed at length on the beauty of early printing and incunabula, the glories of Chinese lacquer, the grace of Japanese carving and the knowledge and appreciation of vintage clarets, each subject being illustrated by valuable examples.

Collie was also a true æsthete, for beauty wherever he found it made a strong appeal to him. During his investigations with Dr. Patterson on the effect of high potential electric discharges on gases at low temperatures, his great friend the late Sir Herbert Jackson said to him, "Collie, I truly believe that you are far more interested in the colours of the discharge than in the striking phenomena you are recording."

As is well known, Collie was an expert rock climber, but he was also a great mountaineer. He climbed many of the Alps, and in 1901, together with Mummery and Hastings, he attempted the ascent of Nanga Parbat in the Himalaya. In 1902, together with Stutfield, he climbed and explored among the Canadian Rockies, where he discovered the Columbia Group. The first expedition was described in "Climbing in the Himalaya", published in 1902, and the second in "Climbs and Exploration in the Canadian Rockies", published in 1903 under the joint names of Collie and Stutfield. Collie was in turn president of the Scottish Mountaineering Club, the Alpine Club and the Royal Geographical Society.

In 1903 Collie invited me to join a party who proposed to climb in the Lofoten Islands. This party included those other great men of the mountains, James Collier, William Cecil Slingsby and Herman Woolley. Under their tuition I learned the elements of the art, and in the following year Collie invited me to join him at Sligachan in the Isle of Skye. There it was my privilege to meet and later to climb with John McKenzie, the guide and ghillie of the hotel. John was a man of fine personality and under Collie's tuition he became a first-rate rock climber. It is true to say that John worshipped the ground on which Collie trod. Whether it were in walking, fishing or climbing, they were inseparable companions, and to those who knew them both it is singularly fitting that Collie was laid to rest alongside John's grave on the shores of Loch Harport, surrounded by the Mountains of the Mist they loved so well.

E. C. C. Baly.

Capt. G. T. McCaw, C.M.G., O.B.E.

Capt. George Tyrrell McCaw, who died on October 17, was the editor of the *Empire Survey Review* and one of the foremost and best known authorities on geodesy in the British Empire.

McCaw was born in Lurgan, Co. Armagh, Northern Ireland, in 1870, and, after a distinguished career at Trinity College, Dublin, graduated in arts and engineering in 1893. From 1893 until 1903 he was employed in the Irish Land Valuation Department, but, in 1903, he accepted an offer to join the Geodetic Survey of Rhodesia under the direction of the late Sir David Gill, at that time H.M. Astronomer at the Cape. This work lasted until 1906, after which he was engaged on the survey of the 30th meridian in Uganda, on the measurement of a base line in Sweden, and then in charge of the Trigonometrical Survey of Fiji, his published report on this survey being a model of what such reports should be.

McCaw returned from Fiji in 1917 and very soon afterwards joined the survey and mapping organization of the British Army G.H.Q. in France, where he acted as geodetic adviser connected with the coordination of the triangulation over the whole front. After the War he became technical assistant at the Geographical Section of the General Staff, War Office, and remained there until he retired in 1936. During this period he also acted as joint secretary of the Colonial Survey and Geophysical Committee and of the Air Survey Committee, his work in the former capacity bringing him into touch with surveyors and geodesists from all over the Empire. On several occasions he attended, as one of the British delegates, meetings of the International Union of Geodesy and Geophysics, and he often spoke at meetings of the Royal Geographical Society when technical matters relating to geodesy or survey were under discussion. He was a voluminous writer on geodetic subjects, and in 1931 he became the first editor of the *Empire Survey Review*, a semi-official journal which was founded under the patronage of the Secretary of State for the Colonies, mainly for the dissemination of technical information among the different Colonial survey departments. The high standard with which he launched this *Review* was maintained, in spite of difficulties caused by the War, until the time of his death. He himself, particularly during the War years, wrote a considerable part of each issue, and most of his contributions contained much matter that was original.

In 1924 McCaw was created O.B.E. (Civil Division) and in 1936, in view of his long connexion, both directly and through the Colonial Survey Committee, with survey matters in the Colonies, and the part that he had played in their development, he was made C.M.G.

Considerable as were his intellectual attainments, McCaw will chiefly be remembered by a very large circle of friends all over the world for his great personal charm, which endeared him to all with whom he came in contact. His advice, constantly sought by young and old, by junior and senior, was at the disposal of anyone who cared to ask for it, and, for that reason, most members of the various Colonial survey departments, when at home on leave, were glad to take the opportunity of calling at his office to discuss with him their own difficulties and problems. He was a most entertaining companion and a loyal and generous friend who was utterly incapable of a mean action.

J. Clendinning.

NEWS AND VIEWS

Joint Council of Professional Scientists

A JOINT COUNCIL of Professional Scientists, representing more than ten thousand qualified men of science, has been set up under the chairmanship of Sir Robert Pickard by the Institutes of Chemistry and Physics in association with representatives of professional botanists, geologists, mathematicians and zoologists. The Council has been established to voice the collective opinion of qualified scientists on matters of public interest, to provide a liaison between professional organizations of scientific men for co-ordinated action in matters of common interest, and in particular to concern itself with: (1) the utilization of men of science to the best advantage in the service of the community; (2) the education, training, supply and employment of scientific workers; (3) the better understanding of the place of men of science in the community; (4) the maintenance of adequate qualifications and ethical standards among professional men of science; (5) the supply of information and advice to public and other bodies on matters affecting men of science.

The members of the Council are as follows: *Institute of Chemistry*: Dr. J. J. Fox, Prof. Alexander Findlay, Dr. G. Roche Lynch, Sir Robert Pickard, Dr. H. A. Tempany, Mr. R. B. Pilcher; *Institute of Physics*: Sir Lawrence Bragg, Prof. J. A. Crowther, Mr. E. R. Davies, Dr. B. A. Keen, Dr. H. Lowery, Dr. H. R. Lang; *Representing Botanists*: Prof. W. Brown; *Representing Zoologists*: Prof. D. Keilin; *Representing Mathematicians*: Prof. S. Chapman; *Representing Geologists*: Prof. H. H. Read. The Joint Council has been established for the period of the national emergency, but it may form the nucleus of some more permanent organization to facilitate the close collaboration between professional men and women practising in all branches of science. Communications to the Council should be addressed to Dr. H. R. Lang, Honorary Secretary, Joint Council of Professional Scientists, c/o The Institute of Physics, at its temporary address, The University, Reading, Berks.

Industrial Reconstruction in Great Britain

A STATEMENT on "A National Policy for Industry" has been issued by a group of 120 industrialists in Great Britain as a contribution to the discussions on reconstruction (*The Times*, November 11). The statement, while urging that, as a producer, industry is by far the largest contributor to the material welfare of the nation, recognizes that industry has a three-fold public responsibility: to the public which consumes its products; to the public which it employs; and to the public which provides the capital by which it operates and develops. The underlying conviction of the whole document is that the spirit which should animate industry is service to the community as a whole, and emphasis is laid on four principles: (1) that the primary duty of industry is to the consumer; (2) that industry should acknowledge by accepting a code of performance towards the workers the partnership of labour in industry; (3) that in any central or sectional organization of industry special steps should be taken to safeguard the interests of small producers; and (4) that whatever form the further organization of industry may take should be and should remain a matter for the determination of Parliament.

The first part of the statement makes a spirited defence of the private enterprise in Great Britain under which industry has shown the essential qualities of imagination, boldness and resource, and the signatories consider that it is a necessary condition of achieving the requisite efficiency that the system of private enterprise continue. It is held nevertheless that the general standard of management can be further improved and that every possible step must be taken to achieve that end. Moreover, industry must recognize its social obligations in contributing to the work of physical reconstruction which will be necessary after the War. In regard to the suggested code of obligations towards employees, the statement refers specifically to co-operation with the trade unions, the development of works councils, holidays with pay, reasonable hours of work, a scheme of family allowances for children, and to part-time compulsory education up to the age of eighteen.

To assure to the consumer the full benefit of technical progress reflected in higher quality or lower prices or both, while establishing greater security for all, the signatories suggest that relations between firms, between different industries and between industry as a whole and Government, should be more fully and comprehensively organized in some form of permanent association. They advocate the classification of industry into sections, each of which should establish a sectional association charged with the duties of co-ordinating the activities and securing the collaboration of all producers in its own section. Beyond this they contemplate a Central Council of Industry representative of the whole of industry in Great Britain. In regard to the specific powers to make regulations and enforce decisions and membership which should be given to the association and Council, the statement points out that this is a matter for the determination of Parliament. It is recognized that ample provision should be made for the protection of the public as consumer, as well as of the small producer, and the establishment of an industrial tribunal or commission is suggested to which appeal could be made.

Colonial Policy

IN the House of Commons on November 26, Sir Edward Grigg moved an amendment to the address in reply to the King's Speech, in which he welcomed the declaration that it is desired to raise the standards of life of peoples in the Colonies, but regretted the lack of mention of specific proposals, including the establishment of a Colonial Development Board. He urged that further arguments about charters and abstract principles are no use, and that machinery should be set up at once to investigate the problems presented by the various Colonies, in order to be able to arrive at an agreed policy on them in relation with other Powers. In the course of the debate, reference was made to the unfortunate effect which may be produced in the Colonies themselves by the frequent changes during recent years in the Colonial Secretaryship.

Mr. Harold Macmillan, Under-Secretary for the Colonies, who replied for the Government, explained that Mr. Oliver Stanley, who has just succeeded Lord Cranborne as Secretary of State, could not be expected to define his attitude immediately. Meanwhile Mr. Macmillan outlined the present position in general terms. As regards the West Indies, he said that £1,500,000 has been spent on schemes under the Welfare Act, and a similar sum provided for the banana industry. Rice production is being developed. In British Guiana a series of drainage schemes are starting which it is hoped will revolutionize rice growing. The most important thing, however, is to attack illiteracy. The growing political consciousness of the Colonial peoples must be developed on sound lines, but the diversity of conditions in the Colonies makes a standardized approach inapplicable. Continuous association of Colonial peoples with their own welfare and development, and co-operation of all concerned, from the highest to the humblest official, in this endeavour, are the methods to be used. Sir Edward Grigg's amendment was then withdrawn.

International Copyright

MR. G. WREN HOWARD and Mr. Stanley Unwin, both of whom are past presidents of the Publishers Association of Great Britain, have issued a statement raising the thorny issue of international copyright. They point out that the last International Copyright Convention, signed at Berne in 1908, afforded a very considerable degree of protection to the literary and artistic property belonging to the nationals of those countries which signed it. The position to-day, however, is that, of the major active members of the United Nations, the British Empire alone is adherent to the Berne Convention. While Germany, Italy and Japan signed it, the United States of America, the U.S.S.R., and the Chinese Republic did not do so. For practical purposes, almost complete protection is enjoyed by the literary property of United States citizens throughout the British Empire, but it is difficult, owing to the conditions imposed, for British subjects to obtain copyright for their property in the United States. Again, while a translation from the Russian into English is copyright in Great Britain and throughout the Empire, no copyright is afforded to any British literary material by the U.S.S.R.; in China, a considerable trade in material reproduced by photographic process has grown up. It is therefore urged that steps should be taken forthwith, as a part of the plans for reconstruction which are under discussion, to introduce a system of international copyright as soon as world conditions permit.

Exhibition of Newton's Books

AN exhibition of books connected with Newton is being held in the Wigan Central Library from November 23 until early in 1943, to celebrate the tercentenary of the birth of Sir Isaac Newton, at Woolsthorpe, Lincolnshire, on Christmas Day 1642. The exhibition was conceived and organized by the borough librarian, Mr. Arthur J. Hawkes. He has managed to bring together from the resources of the Wigan Library, supplemented by a few books on loan, a most interesting collection of early works on science. It includes copies of most of Newton's published scientific papers and books, together with about one hundred works of earlier and contemporary authors bearing on Newton's discoveries. The original issues of the *Philosophical Transactions of the Royal Society* in the possession of the Wigan Library are exhibited, together with the first editions of Newton's "Opticks" (1704), loaned by Messrs. Bernard Quaritch, Ltd., and the "De Revolutionibus Orbium Coelestium" by Copernicus (1543), loaned by the Earl of Crawford. Messrs. Sotheran, Ltd., have loaned the copy of Isaac Barrow's edition of Euclid which was used by Newton as a student at Trinity College and bears many annotations in Newton's handwriting. All the books exhibited carry lengthy notes attached to them explaining their interest and significance in connexion with Newton.

The exhibition was opened on November 23 by Mr. Leonard Stanley Newton, who is a descendant of the Woolsthorpe family. Wigan is to be congratulated on not letting pass, in war-time, the occasion to celebrate the three hundredth birthday of Newton by the exhibition of "so many, and valuable philosophical truths as were never yet discovered and put beyond dispute by the capacity and industry of any one man whatever".

Ministry of Health: Medical Advisory Committee

THE Parliamentary Secretary to the Ministry of Health stated in the House of Commons on November 28 that a Medical Advisory Committee has been set up to advise the Minister on the medical aspects of problems relating to the health of the people. The members of the Committee are:

The presidents of the Royal College of Physicians, the Royal College of Surgeons, and the Royal College of Obstetricians and Gynaecologists; the chairman of Council of the British Medical Association; Dr. G. C. Anderson; Dr. J. C. Arthur; Miss A. Bloomfield; Dr. J. A. Brown; Dr. E. Rock Carling; Dr. J. A. Charles; Prof. H. Cohen; Dr. W. Allen Daley; Lord Dawson of Penn; Dr. E. A. Gregg; Lord Horder; Sir Wilson Jameson (vice-chairman); Dr. W. S. Macdonald; Dr. A. A. Moncrieff; Prof. R. M. F. Picken; Prof. H. Platt; Dr. A. T. Rogers; Dr. D. O. Twining; Dr. O. Williams; and Miss A. L. Winner.

Imperial Institute of Entomology

SIR GUY MARSHALL retired recently from the post of Director of the Institute and has been succeeded by Dr. S. A. Neave. The work of the Institute is well known. It publishes the *Review of Applied Entomology* and the *Bulletin of Entomological Research*, identifies insects submitted by entomologists from all parts of the world, distributes collections of named insects, provides initial stocks of parasites of economic importance, and acts generally in an advisory capacity and as a clearing house for matters connected with applied entomology throughout the Empire. A vacancy on the staff has just been filled, but there will be two others within the reasonably near future, and suitable candidates for these posts are now being sought. Further information can be obtained from the Secretary, Imperial Agricultural Bureaux, 2 Queen Anne's Gate Buildings, London, S.W.1, and applications made by May 1.

Bicentenary of Nicolas Leblanc

AMONG the world's benefactors whose discoveries have been ill-requited by their fellows was the French surgeon and chemist, Nicolas Leblanc, who was born at Ivry-de-Pré in the Département of Cher on December 6, 1742. Though of poor middle-class parents, he was able to study medicine at the Collège de France and ultimately became surgeon to the unfortunate Louis-Philippe-Joseph, Duke of Orleans. In 1775 the Paris Academy of Sciences offered a prize of 2,400 livres for a practical process of producing soda from common salt. By 1787 Leblanc had solved the problem, and through the generosity of the Duke was enabled, with Dizé, to erect a factory at St. Denis, and in 1791 a patent was granted him. In

1793, however, the Duke fell beneath the guillotine, and the factory was confiscated. Though in later years the factory was restored to Leblanc, together with a small monetary recompense, it was all in vain. Leblanc struggled hard against his misfortunes, but at the age of sixty-three his mind gave way and on January 16, 1806, he committed suicide. His process, however, gradually came into use and in 1883 Dumas, speaking to the Paris Academy of Sciences, said that the annual consumption of carbonate of soda in Europe and America, produced by Leblanc's process, was then estimated at between 700,000,000 and 800,000,000 kgm. In spite of this, little was known of the discoverer. Four years after Dumas spoke, a bronze statue of Leblanc was erected in the forecourt of the Conservatoire des Arts et Métiers in Paris.

Simplified Electrically Heated Hotbeds

A REPORT. Ref. W/T7, by C. A. Cameron Brown and E. W. Golding, issued by the British Electrical and Allied Industries Research Association, describes experiments carried out to determine whether a simple method of heating hotbeds electrically can be applied successfully to the intensive production of early salad crops in small frames such as are used by non-professional growers. The method consists essentially in equipping a frame with a soil-heating cable or with a transformer-fed bare iron wire to give a loading of 2–5 watts per sq. ft. Heating is controlled, from a convenient point in the domestic premises from which supply is taken, to give certain regular 'doses' of heat in each 24-hour period. These doses vary from 40 to 45 watt-hours per sq. ft. per day, depending on the district. The two most convenient modes of procedure appear to be either with a loading suitable for all-night running or with a lower loading suitable for continuous running. The method is designed for operation on the domestic two-part tariff and to take advantage of the low running charges available. The experiments have shown that the method is a practical and economical way of producing lettuces of first-class quality from mid-March onwards, with little attention and at a total cost, including overhead charges, well below the current retail prices in shops. While early lettuce is the main crop, other crops can be raised, either simultaneously, such as carrots, or in succession, thus adding to the value obtainable from the hotbed installation.

Tuberculosis in the United States

ACCORDING to the *Journal of the American Medical Association* of September 26, the United States National Tuberculosis Association has reported that 44 persons per 100,000 of population died of tuberculosis in 1941, as compared with 46 in 1940. In 1941 the deaths from tuberculosis in the United States amounted to 59,173, and 105,714 fresh cases were reported. The highest tuberculosis death-rate occurred in Arizona (171 per 100,000). Other high rates per 100,000 reported were in the District of Columbia (82), Tennessee (79), Maryland (74), Kentucky (67) and New Mexico (65). The lowest death-rate reported was from Utah (11). Other States with a rate far below the national average were Wyoming (13), Iowa (15), Nebraska (15), Idaho (16), North Dakota (18), New Hampshire (21) and Kansas (22). New York State reported 6,208 deaths —a rate of 45·5.

New Zealand Earthquakes

DURING August 1942, ten strong earthquakes were registered by the seismographs at Wellington, Auckland, Christchurch, Arapuni, New Plymouth and Tuai in New Zealand (*Prov. Bull.* No. P.126, New Zealand Seismological Report; Dominion Observatory, Wellington, N.Z., 1942, August). The earthquake on August 1 was a local shock, namely, the Wairarapa Earthquake, and that on August 29 had an estimated depth of focus near 600 km. Altogether there were twenty-three local shocks felt in New Zealand during the month, of which by far the strongest was that on August 1 at about 12h. 34·1m. U.T. with epicentre near lat. 41·0° S., long. 175·8° E. This was felt from near Auckland to Dunedin and Queenstown, and in parts of Wairarapa had an intensity of rather more than 8 on the Rossi-Forel scale.

History of Science

IN Catalogue 70, Messrs. E. F. Goldsmith and Co., of 45 Old Bond Street, London, W.1, are offering for sale the library of Prof. A. Wolf, formerly professor of the history and philosophy of science at University College, London, and some new acquisitions, amounting in all to 834 items. The catalogue includes works on anthropology, astronomy, biography, biology, botany, chemistry, mathematics, optics, philosophy, psychology and statistics. Among the outstanding volumes are the first edition of "Astronomici Veteres" (1499), Tycho Brahe's "Epistolæ Astronomicæ" (1595), Simon Stevin's "Œuvres Mathématiques" (1634), Scheele's "Chemical Essays" and Volta's "Collezione dell' Opere" (1816). Modern writers are represented by numerous works of Einstein (including his "Brief Outline of the Development of the Theory of Relativity" from the special issue of NATURE on Relativity published on February 17, 1921), Freud, Galton, Karl Pearson and J. J. Thomson.

Announcements

MR. ORVILLE WRIGHT, of Dayton, Ohio, has been elected an honorary member of the Institution of Mechanical Engineers in recognition of his distinguished contributions to mechanical science. Through many years of patient and productive experiment Mr. Orville Wright, with his late brother Wilbur Wright, developed an aeroplane, with wing sections, motor, and controls, which made possible the flight of Orville Wright in 1903.

PROF. G. P. THOMSON, professor of physics in the Imperial College of Science and Technology, is to deliver the May Lecture for 1943 of the Institute of Metals. His subject will be "Electron Diffraction". It is of interest to recall that his father, the late Sir J. J. Thomson, delivered the Institute's May Lecture in 1915, speaking on "The Conduction of Electricity through Metals".

THE Faculty of Science of Marx House, London, organized a symposium on "Science and Technology in the Soviet Union" which was held during April 5 and 6 last (see NATURE, April 18, p. 426, and May 16, p. 545). Articles based on papers presented at these meetings by Prof. J. D. Bernal, Mr. H. P. Vowles, Dr. N. F. M. Henry, Mr. H. Rose, Dr. M. Ruhemann and Mr. J. L. Fyfe have now been brought together in a pamphlet, obtainable from the Organizing Secretary, Marx House, 1 Doughty Street, London, W.C.1, price 2*s*.

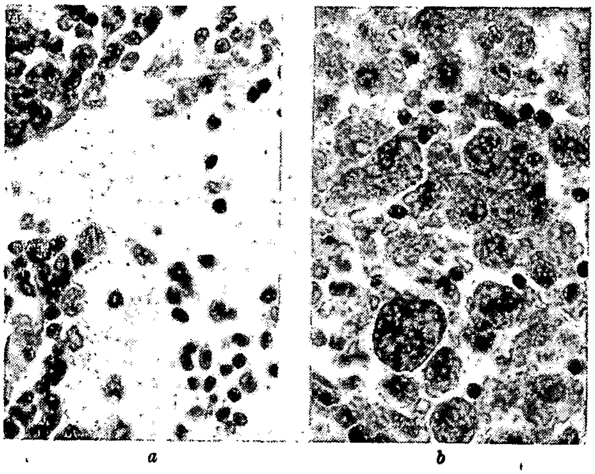
Formation of Hæmolymph Nodes in Rats Treated with 1 : 2 : 5 : 6-Dibenzanthracene

Previous investigators[1-4] have described the spontaneous occurrence of hæmolymph nodes in the rat. As a rule, two nodes situated in the vicinity of the kidneys were found to be the most conspicuous representatives of these structures. Their histological features were studied in detail by these workers ; but much uncertainty exists as to the origin and possible function of such nodes, and the same applies to those observed in other species of mammals. It is obvious that useful information might be obtained from experiments aiming at the conversion of ordinary lymph nodes into hæmolymph nodes, and our investigations in this field have led to a number of results, some of which appear to be conclusive. This note describes the effect produced in the lymph nodes of rats by treatment with the carcinogenic hydrocarbon 1 : 2 : 5 : 6-dibenzanthracene, the experiments being suggested by previous observations on rats treated with carcinogenic tar[5].



PART OF THE CENTRAL SINUS OF A CERVICAL LYMPH NODE. *a*, from a control rat; *b*, from a rat treated with 1 : 2 : 5 : 6-dibenzanthracene. Hæmatoxylin. × *c*. 340.

The hydrocarbon was administered in an aqueous colloidal solution, 27·8 mgm. (that is, 0·1 milli-mole) being dispersed in 100·0 c.c. of a solution of 5·6 per cent glucose and 0·5 per cent gelatine. 1·0 c.c. of this liquid was injected subcutaneously into a series of male pre-adult rats usually five times weekly for a period of about four weeks. This treatment was on the whole well tolerated. For comparison, other rats of similar weights were treated with a control solution (glucose-gelatine medium only), injected in a corresponding manner.

It was found that while the lymph nodes from the control rats were throughout of normal appearance, a number of the lymph nodes from the dibenzanthracene-treated rats showed a red or brownish-red discoloration on their surface, varying in extent and degree. A hæmolymphatic transformation of these nodes was thus indicated. The change occurred in all regions of the body ; its intensity—as regards the number of affected nodes and the amount of dis coloration in individual nodes—tended to increas with the duration of treatment, and appeared to b even greater some time after its termination. O microscopical examination, the following principa changes were observed in the structure of these node as compared with the nodes from control animals (1) a more or less distinct widening of the lymp spaces and corresponding diminution of the lymphati tissue ; (2) the presence in these lymph spaces o red blood corpuscles, frequently in considerabl numbers ; (3) an increase in the number of fre macrophages loaded with red blood corpuscles and greenish-brown pigment which, on applying th microchemical test for free iron, proved to be 'hæmo siderin'. From the latter findings it is evident tha the red cells present in the lymph spaces underg a process of destruction. An illustration of thes histological changes (stated under 2 and 3) is give by the two accompanying photomicrographs, take at high magnification. Part of the central sinus of cervical lymph node is shown in each, (*a*) referring t a control animal and (*b*) to a dibenzanthracene treated animal. It will be seen that in (*a*) the cel content of the sinus is confined to a number o lymphocytes and reticular cells, while in (*b*) the sinu contains in addition many red blood corpuscles a well as a number of free macrophages carrying bloo corpuscles and pigment. It is to be noted that th histological changes thus observed agree essentiall with the histological features of the renal hæmolymp nodes occurring already in control rats.

A detailed account of this work will be publishe elsewhere. Further investigations are in progres regarding the possible action of two other carcinogeni hydrocarbons (3 : 4-benzpyrene, methylcholanthrene and two related non-carcinogenic hydrocarbon (anthracene, phenanthrene), both groups of substance being employed in a similar manner to 1 : 2 : 5 : 6-dibenzanthracene. So far, it has been found tha hæmolymph nodes can be formed in rats treated with either of the two carcinogenic hydrocarbons, while no appreciable changes seem to occur in the lymph nodes of rats treated with either of the two non-carcinogenic hydrocarbons. These results, if confirmed by subsequent work, might indicate that the ability of a polycyclic hydrocarbon to produce hæmolymph nodes in the rat is in some way connected with its ability to produce cancer.

Partial Purification of Cell Growth-Promoting Principles in Adult Tissue Extract

In a previous note from this Laboratory[1], it was reported that extracts of heterologous adult tissues possess the ability to stimulate *in vitro* the growth of various cells including human epithelium, and the use of adult tissue extracts in wound treatment was suggested. We report below the results of experiments carried out to purify the growth-promoting principles present in adult tissue.

Minced heart muscle of sheep or fowl was extracted with five parts of physiological saline solution and the extract precipitated with four volumes of 96 per cent alcohol. The precipitate was centrifuged and then dried over calcium chloride *in vacuo*. The dry product represents about 5 per cent in weight of the original material. It is slightly soluble in Ringer, better in Tyrode, and more readily in 0·01 *N* ammonium hydroxide. The growth of fibroblast cultures in a medium to which the solution of the alcohol precipitate in Tyrode is added is stimulated to the same degree as the growth of cultures treated with the original heart muscle extract. Repeated extraction of the dried alcohol precipitate with either acetone, ether or petroleum ether led to improvement of the stimulating power. Dialysis of solutions of the alcohol precipitate against Ringer did not affect their activity.

An ammonia solution of the alcohol precipitate was neutralized and precipitated by half-saturation with ammonium sulphate. The sediment was dissolved in dilute ammonia, carefully dialysed, and the solution evaporated *in vacuo* to dryness. The product thus obtained was almost entirely soluble in Tyrode and displayed good growth-promoting properties.

These experiments are only a first step. Nevertheless, their publication seems desirable, as during the course of this work alcohol precipitates possessing great cell-promoting power have been obtained. These preparations may represent a particularly appropriate material for experiments in wound healing. It combines with high potency the following practical merits: its preparation does not require sterile precautions except at the final stage; its storage is convenient and its stability is unlimited.

Preservation of Plant Material

PRESERVATION of botanical material for teaching purposes is frequently necessary and is commonly achieved by keeping the material in alcohol. With whole plants, or bulky organs, for example many succulent fruits, large quantities of alcohol are required.

Satisfactory preservation may be obtained with many types of material by using a solution of sulphur dioxide, and this method has much to recommend it on the scores of convenience and economy. The use of sulphur dioxide as a preservative of fruits and fruit products for domestic and industrial use is well known. For domestic use "Campden Tablets", consisting of sodium or potassium metabisulphite, may be employed, each tablet as purchased containing the equivalent of 4 grains of sulphur dioxide, so that when dissolved in water (½ pint or 10 oz.) a solution containing approximately 0·1 per cent sulphur dioxide is obtained. This solution preserves most succulent fruits required for morphological studies satisfactorily. It has also proved adequate as a preservative of material required for anatomical work by elementary classes. Any slight hardening effect of the solution is not a disadvantage when herbaceous material is employed, and sections of the preserved material stain normally with common stains such as aniline chloride, iodine and phloroglucin. Anthocyanin pigments present are 'bleached' by the solution, but the blackening to which some plants, for example broad beans, are prone is prevented.

Directions for the use of the "Campden Tablets" include instructions to cork the bottle tightly, and to seal with wax. In fact, tight corking is generally sufficient, but frequent opening of the container in order to remove material is not permissible, as this allows oxidation of the sulphur dioxide and subsequent growth of mould. This is not a disadvantage when preservation of material for use on a subsequent single occasion is required, and even this trouble might be obviated by the addition of a tablet of preservative whenever the bottle has to be opened. Occasionally with fruits containing little free acid slight fermentation occurs[1] but fruits, flowers, stems and leaf material in freshly made solution, and in tightly corked containers, have all kept satisfactorily here.

In field use the method is convenient as the tablets are easily carried, and bottles of ½ pint (10 oz.) capacity or some multiple of this are obtainable in almost every locality and need only to be filled with water and tablets added at the rate of one to each ½ pint of water.

Clearly the adoption of this method of preservation results in the saving of an appreciable amount of alcohol, and at present this alone may well outweigh slight disadvantages that the method possesses.

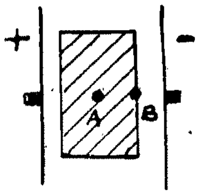
Validity of the Clausius-Mosotti Formula

IN a paper published in 1940[1] I threw doubt on the validity of what is now called the Clausius-Mosotti formula and put forward another which, if correct, would considerably affect present values of the dipole moments of many substances.



In that paper I stressed the confusion between macroscopic and microscopic treatments of the problem. The difficulty may, perhaps, be seen more clearly from the following treatment of the usual case of a plane slab of polarizable material placed in the uniform field of a charged condenser as shown in the figure.

Consider the alternative cases, (1) the molecules are uniformly polarized; (2) the molecules are not uniformly polarized.

(1) If the molecules are supposed all uniformly polarized (and this can be proved only on the macroscopic view), there is no difference between the polarizing field at A and that at the boundary B. There is therefore no need to calculate the force E at A and say that, if the polarizability is α, then the moment of a molecule at A is αE. The moment at A is the

same as at B, and as B is on the boundary, this moment contributes to Poisson's Layer of surface density σ. If there are n molecules per cm.^{3} we have at once

$$\sigma = \text{electric moment per unit volume} = n\alpha E.$$

To relate this result to what is actually measured, namely, the drop in potential when the slab is introduced, we imagine a channel cut through the dielectric so that a unit positive charge may be taken from one plate to the other through it. If E_A is the intensity before the dielectric is inserted, the force in the channel is $E_A - 4\pi\sigma$, and experiment shows that this must be assumed to be E_A/K, since the potential drops to $1/K$ of its vacuum value, where K is the dielectric constant. Thus :

$$E = E_A - 4\pi\sigma = E_A/K = \sigma/n\alpha, \text{ whence } K = 1 + 4\pi n\alpha.$$

(2) If the molecules are supposed not uniformly polarized (and this must be the case on a microscopic view, since the polarizing force at A must differ from that at B owing to the different arrangement of surrounding molecules), then Poisson's volume distribution of charge must be taken into account as well as the surface layers in order to calculate the force at the centre of a spherical cavity. This is never done, and it could not be done for lack of information as to how the polarization varies from point to point. The treatment which Clausius gave is therefore not valid.

The conclusion seems to be that only a macroscopic treatment can be applied and that the formula should be

$$K = 1 + 4\pi n\sigma.$$

Thus for the molar polarization P we should have

$$P = \frac{K-1}{3} \cdot \frac{M}{\rho}$$

instead of Clausius-Mosotti

$$P = \frac{K-1}{K+2} \cdot \frac{M}{\rho}$$

(M is molecular weight, ρ is density).

Shape of Subjective Space

THE apparent alteration in the size and shape and spatial relation of objects when right-eye and left-eye viewings are interchanged (or in other way the binocular parallax is reversed) may prove to some degree dependent on retinal structure, as suggested by Mr. Cox[1], but considerable alterations of like character are certainly accounted for by peculiar geometrical conditions, in conjunction with extreme quickness of the eyes and mind to interpret these as normally as possible.

More than ten years ago, I directed general attention to the astonishing effect of viewing the Hyades or Orion's Belt, or similar bright star group, through a common inverting binocular, when the stars are behind a familiar object like the bare twigs and branches of a tree, or the figure of a man, a little way off. To most observers with normal sight the stars appear in the air half-way to the tree, which in some cases may mean only a yard away through the binoculars. That provides or points out the general illustrative kind of case for such phenomena, even for the naked eyes, though the effects are rather feebly noticeable at long distances when telescopes are not used.

Briefly, explanations of the half-way appearance may be arranged like this: The distance d of the tree is assessed at once, in the ordinary view, by convergence (so far as the distance is short) and by the angular subtense which the tree shows as a chosen familiar object. After the reversal of parallax there is no natural convergence at all to use (only eye-straining divergence), but most observers still assess d well enough by the angular subtense. The ordinary relative parallax of the tree and heavens is like $\frac{1}{d} - \frac{1}{\infty}$. After reversal it is similarly like $\frac{1}{x} - \frac{1}{d}$, where x is the apparent distance of the heavens, a distance now less than d because of the reversal. Of course $\frac{1}{x} - \frac{1}{d} = \frac{1}{d} - \frac{1}{\infty}$, so $x = d/2$, and that the eyes and mind instantly recognize, after their lifelong experience of similar parallax problems. Only to the extent the object is not familiar, or not single and distinct but confused, may the observer not promptly recognize d, and then it is that the heavens are found reluctant to leave their usual remoteness. The telescopes of magnification m make x as small as $d/2m$; and they also aid by their ordinary telescopic flattening of the tree. The interchange of the far and near parts of the tree is curious but not very important. When the sun (or moon) is in view with the tree, the linear diameter of the sun appears as small as $d/230$ feet, which is sometimes as little as two or three inches. Intrusive twigs make a transparency effect.

It is evident that the subjective spatial change in this example is remarkable. The whole universe ha in effect been turned inside out at the dictate of the tree and its scale-fixing distance d. The outermost parts towards infinity have been brought in to a spherical surface of only $d/2m$ ft. radius around the observer, and parts nearest the observer have been dispersed towards infinity. Accordingly, to some observers in clear air over a featureless plain, dozens of men ranged in line from as near as th tree, outwardly to the horizon, appear as dwarfs nea at hand tapering outwards to become giants in th distance. Perhaps because the dwarfs are mor crowded, numerous and uninteresting, normality usually seems allotted to them, and magnification is declared the chief impression. Possibly causes o similar kind might be found involved in some of the magnification effects which have come under Mr. Cox's notice.

The mind's instant, unhesitating use of the eye and former experiences, or memory, as instrument in these subjective phenomena is noteworthy. The geometry and the eyes cannot prove the whole o the interest. In that connexion, regard should certainly be had to Sir Richard Paget's communication in NATURE of July 22, 1939, p. 153.

RESEARCH ITEMS

Schooling of Mackerel

ARTHUR SCHLAIFER has made some interesting experiments ("The Schooling Behavior of Mackerel: A Preliminary Experimental Analysis". *Zoologica.* Scientific Contributions of the New York Zoological Society, 27, Part 2, No. 14; 1942). These were carried out at the Woods Hole Station of the U.S. Fish and Wildlife Service. The fishes used were 8-in. specimens of the chub mackerel, *Pneumatophorus grex* (Mitchell), caught in the waters off Woods Hole and afterwards kept in large tanks in the laboratory. It was found that two individuals suffice to form a school, swimming always in line with each other. If one mackerel is kept isolated and another is put in with it, the two immediately school and any others added join them. Schooling is seen still better in larger groups. Blinding, darkness and visual contact experiments indicate that the schooling reaction of the mackerel is visually integrated. Mackerel display no schooling reaction to others of the same species, dead or alive, which move or are moved in a manner not completely normal. Apparently there is no response to body colour. Isolation for three weeks does not eliminate or reduce the schooling proclivity. Good photographs are given of mackerel in fairly strong artificial light, in total darkness and in light in the deep red end of the spectrum.

Biology of a Carnivorous Snail

WILLIAM MARCUS INGRAM gives some interesting notes on *Euglandina rosea*, a well-known species common on the sea islands of Georgia and around the Keys of Florida ("Food, Eggs and Young of the Carnivorous Snail *Euglandina rosea* (Férussac)". *Zoologica.* Scientific Contributions of the New York Zoological Society, 27, Part 2, No. 15; 1942). A specimen was kept in a terrarium and laid eggs there. Experiments in feeding resulted in its eating the molluscs *Mesomphix inornatus* and *Anguispira alternata*, leaving untouched another species of Mesomphix, *M. cupreus*, and young and adults of *Triodopsis albolabrus*. It is evident that there is definite selection here. The method of feeding is described, the snail devouring the whole of the living prey from inside the shell. When completely inert it reacted directly to the food selected, and although ten inches away it was moving towards it within three minutes. All the molluscs eaten were first turned over on their apices. Twenty-two eggs, laid on the upper surface of the humus in the terrarium, exposed to the light, were about 3 mm. in length with hard calcareous shells. The approximate incubation period was 60-68 days, when the young broke through the shell by means of the radula.

Germ Cell Inclusions

THE investigations into the cytoplasmic inclusions in the germ cells of the mouse by Dr. R. A. R. Gresson have been continued in two further publications. One deals with the inclusions found during the maturation, fertilization and first cleavage division of the ovum (*Quart. J. Micro. Sci.*, 82, Pt. 4; 1942) and the other with those found during spermatogenesis (*Proc. Roy. Soc. Edin.*, B, 61, Pt. 2; 1942). The Golgi elements appear to be fairly evenly distributed throughout the period from maturation to the formation of the first two blastomeres. The mitochondria are most numerous in the central region during maturation divisions, a few being eliminated with the polar body. During the stage of the pronuclei they concentrate in the neighbourhood of these structures and they congregate around the first cleavage spindle in such a manner that they are distributed approximately equally to the two blastomeres, where they gather into small clumps and are then scattered singly throughout the cytoplasm. In the spermatogonia and spermatocytes the Golgi elements are situated at one pole of the nucleus; during division they remain near the equatorial region of the nucleus and either as two clumps or dispersed they are distributed to the daughter cells. In the young spermatids they are applied to the anterior pole of the nucleus but move away, leaving a vacuole, later filled by the acrosome, then bud off a small portion which moves to the posterior pole and this is later included in the middle piece of the sperm. The spherical mitochondria are most numerous in the neighbourhood of the nucleus in spermatogonia and spermatocytes, and in the transformation of the spermatid into the spermatozoon most of them come to lie around the axial filament. The sperm enters the ovum at the anaphase of the second maturation division.

Parasites of Horses

A USEFUL account of the nematode parasites of the horse belonging to the family Strongylidæ as of Baird 1858 is furnished by Dr. W. A. Rosa and Dr. E. J. Galofre (*Inst. Parasit. Enfer. Parasit. Univ., Buenos Aires*, 1, Fasc., 6; 1940). The 19 species treated are divided among four genera: Strongylus 3 spp., Triodontophorus 2 spp., Trichonema 13 spp., and Gyalocephalus 1 sp. The introductory portion consists of a good general account of the anatomy and classification of the family. The remainder of the paper consists of a series of plates, one for each species, of drawings to scale of the diagnostic and comparable parts of both sexes of the strongyles. The plates are accompanied by fully annotated explanations and measurements, so that it should render the identification of any of the species comparatively easy.

Genetics of the Sorghums

IN a series of notes originating from the Millets Breeding Station, Coimbatore, G. N. Ayyangar and various co-workers describe the mode of inheritance of a number of characters in the Sorghums (*Current Science*, pp. 491, 492, 528 and 533; 1941). One of the most interesting is a dominant mutation for purple anther base (A_b), detected in the heterozygous condition in *Sorghum dochna* and later found to be due to a single gene closely associated with one of the two B genes for brown pericarp colour. The independent genes C_1 and C_2 behave as simple dominants and deepen the light green of normal lines, thus accounting for the dark green (C_1C_2), green (C_1c_2 or c_1C_2) and light green (c_1c_2) noted in the blocks of plants forming the World Collection of Millets at Coimbatore. The curious habit of 'goose-necking' (bearing heads on recurved stems) shown by some of the Sorghums is brought into line with genetical observations. The recessive gene wy results in a wavy peduncle to the inflorescence: this condition in a plant having a naturally short peduncle causes the ear to twist and escape out of the side of the last leaf (the 'boot') and so become bent into a 'goose-neck'. The relatively rare long type of hairs found on the glumes of *S. dochna* var. *burmaniium*, *S. Roxburghii*, *S. caffronum*, *S. coriaceum* and *S. cernuum* are described as due to an independent dominant gene *Gf* which lengthens the hairs produced by the gene *Gh* for the normal hairy condition. *GfGh* results in long hairs, *gfGh* the normal hairy condition and *Gfgh* or *gfgh* 'glabrous'.

Structure of Urea and Thiourea

Previously reported values for the dipole moment of urea (8·6) and thiourea (7·6) are unexpectedly high in comparison with those of related compounds, and these constants have been redetermined in dioxane as solvent at 25° by W. D. Kumler and G. M. Fohlen (*J. Amer. Chem. Soc.*, 64, 1944; 1942), who find the values 4·56 and 4·89, respectively, which fall in line with those of similar compounds. The molecules were not associated in these solvents. The results throw some light on the old controversy as to whether urea and thiourea are amphions. This was at first taken to imply the structure  $\bar{\mathrm{O}}-\mathrm{C}\begin{matrix}\nearrow\mathrm{NH}\\ \searrow\mathrm{NH}_3+\end{matrix}$ but later $\bar{\mathrm{O}}-\mathrm{C}\begin{matrix}\nearrow\mathrm{NH}_2+\\ \searrow\mathrm{NH}_2\end{matrix}$, involving a separation of charge but no proton transfer, and thus a resonance hybrid. The moderate values of the dipole moments show that such structures do not contribute predominantly to the state of the molecule. The short C to N distance has been supposed to indicate an amphion structure, but this amounts only to about 20 per cent of double bond character. The fact that the ratio of the solubility of urea in alcohol to its solubility in water is much higher than for an amino-acid with an amphion structure also makes such an ion structure in alcohol improbable. It seems as if everything can be accounted for by about 20–30 per cent of amphion structure, the essential structure of urea and thiourea being that of simple amides except for a somewhat larger contribution of the forms with a separation of charge.

Structure of Galactic Clusters

George Alter has a paper on the structure of galactic clusters (*Mon. Not. Roy. Astro. Soc.*, 102, 4) deducing a number of important tentative conclusions. He starts by assuming that the structure of a galactic cluster depends on the development of the cluster, which is of two kinds: (*a*) the dynamical evolution of the whole unit; (*b*) the spectral evolution of the individual members. Trumpler proposed a hypothetical evolution of clusters, which was based on a detailed classification according to the presence of yellow or red giant stars and the earliest star type within the cluster, and Alter simplifies this by a regrouping into four classes. It is suggested that clusters develop from the giant cool class through the giant hot and main hot to the main cool class, but with a certain indeterminacy near the central classes, where short transitions may occur. From a number of tables it is shown that the relations between these four classes and various structural properties of galactic clusters support the suggested scheme of classification. It is believed that the clusters develop along a life-line similar to that of the Russell diagram, and during this evolution the clusters are subject to the influence of the galactic field. The initial volume of 10–100 cubic parsecs increases until disintegration leads to the loss of stars merging with the surrounding star field. The lowest recognized average spatial star density within a cluster is about five times that of the star density in the vicinity of the sun, and the highest is about 250 times as much. The true values are actually higher, and this is explained by the star numbers used for determination being restricted by the magnitude limit of the photograph. The largest observed volume is about 1,000 cubic parsecs.

Voltage Surges Caused by Contactor Coils

A paper on this subject by J. R. Taylor and C. E. Randall, read before the Institution of Electrical Engineers, discusses the phenomena associated with the switching of contactor coils, particularly with reference to the effects of 'switching peak' voltages on insulation and switch contacts. The effect of circuit layout on the switching peaks and the arcing of contacts is described, together with methods of reducing the severity of these effects. Owing to a series of insulation breakdowns, it was decided to make an investigation of the switching-off voltages of a D.C. contactor coil. Early experiments were merely qualitative, but later, equipment was built for quantitative tests. Photographic records of the various phenomena were made in order to give a clear picture of the different conditions which are met. Peak voltages up to ten to fifty times the supply voltage occurred. Eventually it was decided to extend the research to A.C. contactor coils, and peak voltages up to five to six times the mains voltage peak were found to occur under favourable conditions. It is obvious from the tests that clearances which are satisfactory for electric lamps on 230 volts are totally inadequate for coil circuits even on 100 volts, and that on higher voltages it is essential to have large clearances and creepage distances. Instances are known of sparks jumping distances of as much as ½ in. along the surface of slate on control panels connected to 530-volt tramway supplies.

Grid-Controlled Mercury-Arc Mutators

R. Feinberg, in a paper entitled "Static Conversion of Direct Current to Alternating Current with Grid-Controlled Mercury-Arc Mutators" (*J. Inst. Elec. Eng.*, 89, Pt. 1, No. 22; October 1942), deals with the theory of the push-pull mutator invertor, which is a D.C. arrangement with grid-controlled mercury-arc mutators operating alternately and causing an alternating current to flow in the load circuit. In the case of resistance load, practically any shape of alternating voltage wave-form between rectangular form and triangular form can be produced. The shape of the alternating voltage wave-form depends upon the capacitance of the invertor capacitor, a relatively small capacitance giving the alternating voltage a rectangular form and a large value making it triangular. The ripple factor of the direct current is governed by the smoothing effect of the inductance in the D.C. circuit, a small inductance causing the direct current to flow intermittently. The degree of regulation of alternating voltage at any change of load is determined by the capacitance of the invertor capacitor. A large capacitance may produce such a large voltage regulation that the curve of power output plotted against load describes a V form, the power output being increased when the load is reduced. The invertor stops working when overloaded. Calculations are given for approximate circuit conditions, and the results of experiment have been found to agree satisfactorily with the theory.

MEDAL AWARDS OF THE ROYAL SOCIETY*

Copley Medal

THE Copley Medal has been awarded to Sir Robert Robinson, Waynflete professor of chemistry in the University of Oxford.

Sir Robert Robinson is recognized in all countries as one of the world's leaders in organic chemistry, and is one of the greatest and most versatile of investigators in that department of science. His researches, with a long and notable succession of pupils and collaborators, have covered a remarkably wide range of problems in this field, and his approach to these has been distinguished by brilliance in conception and a genius for the selection of methods leading to the desired solutions. Robinson's investigations have been particularly concerned with the chemistry of natural substances, products of the life processes of plants and animals. His work has thus been a potent factor in the tendency of organic chemistry to return, in recent years, to an objective nearer to that of its origin, and to make contacts of growing intimacy and value with biochemistry, a more recent development in response to the stimulus of functional biology.

This occasion does not permit any attempt at a complete or detailed survey of all the different fields which Robinson's work has illuminated and opened to further exploration. Special mention must be made, however, of his long series of fundamental investigations on the constitution and relationships of the plant alkaloids. His theory of the biogenesis of plant products seems rather to have inspired than to have resulted from his own early and elegant synthesis of tropinone; and it has revealed an unforeseen and coherent relationship between the constitutions of different groups of alkaloids, and given a great stimulus to work on their synthesis. The work published from Robinson's laboratory has been fundamental to understanding of the isoquinoline and the indole series of alkaloids, of morphine and its allies, and of the structural formulæ of strychnine and brucine, which formed the subject of his Bakerian Lecture.

Of at least equal scientific rank is the work which Robinson carried out and inspired over many years on the anthocyanin and, more recently, on the anthoxanthin pigments of plants, culminating in the synthesis of the actual colouring matters of flowers, and forming as a whole one of the most brilliant achievements in the whole range of modern organic chemistry.

Robinson's mastery of synthetic resources, and his penetrating instinct for clues to organic constitution, have been further demonstrated in a more recent approach to the synthesis of the steroids, in the production of series of compounds of interest for chemotherapy, and in notable studies of individual natural substances of a range of other types. He is, moreover, a philosopher as well as a master of experimental possibilities; and his theory of organic reactions, in the modern, electronic terms of valency bonds, has had a great influence on the development of fundamental conceptions in organic chemistry.

The Copley Medal is the highest recognition of scientific achievement in the Royal Society's gift, with no limitations of subject or nation; and the Society may well find cause for satisfaction in the knowledge that the award of its premier medal, this year for achievement in organic chemistry, after an interval of many years, finds among its own fellows a recipient of such unquestioned pre-eminence as Sir Robert Robinson.

Rumford Medal

The Rumford Medal has been awarded to Dr. G. M. B. Dobson, reader in meteorology in the University of Oxford.

The Rumford Medal awarded by the Royal Society was established for the recognition of important discoveries made in Europe, especially on heat or on light. These conditions appear to be met with a special fitness in the award of the Medal this year to Dr. G. M. B. Dobson, for his meteorological researches and discoveries. For Dobson's work has, in recent years, greatly extended knowledge of the linkage between the behaviour of ozone and cyclonic disturbances, in that complicated heat engine which is the earth's atmosphere; while light may be said to have provided the basis of measurement for Dobson's spectrographic studies of the distribution of ozone, in time and in height above the earth's surface.

Light had also a major concern in earlier researches on meteors in which Dobson collaborated with Prof. F. A. Lindemann (Lord Cherwell); in these, the study of the heights between which meteors become luminescent enabled them to draw conclusions as to the density, and from these as to the temperature of the atmosphere at great heights from the earth's surface. But it is especially on Dr. Dobson's own studies of the ozone of the atmosphere, continued over many years, and producing results of outstanding importance for meteorology, that the award is based.

Royal Medals

A Royal Medal has been awarded to Prof. W. N. Haworth, professor of chemistry and director of the Chemistry Department in the University of Birmingham.

Haworth's great claim to distinction arises from the revolutionary change which has been produced by his own investigations, and by those of his immediate pupils, in the whole aspect of an important section of organic chemistry, dealing with the structure and the relationships of the carbohydrates. The ring structure of the simple sugars, first proposed by Tollens and supported by the work and the authority of Emil Fischer, had been generally regarded by chemists as firmly established. Detecting insecurities in the arguments which led to this formulation, Haworth developed the methylation technique, first used by Purdie and Irvine, and applied it systematically to the monosaccharides. He was thus able to show, by unequivocal methods of organic chemistry, that the accepted ring structure of these sugars was incorrect, and that, in their normal and reactive forms, they were derivatives of pyran and of furan respectively.

Later, Haworth further developed his methods in application to sugars and carbohydrates of increasing complexity. By his work, and that of others who have followed his lead, the detailed structures of many disaccharides and of some trisaccharides have been established. Progress has further been made in his attack on the structural complexities of the polysaccharides, and a simple chemical method has been evolved for determining their minimal molecular weights. Prof. Haworth's work, in the field which he has thus made his own, has received the high international recognition of a Nobel Prize, and will assuredly take rank as a major achievement of permanent significance in chemical history.

---

* Remarks made by Sir Henry Dale, Pres.R.S., in presenting the medals for 1942.

A Royal Medal has been awarded to Dr. W. W. C. Topley, formerly professor of bacteriology and immunology, University of London, now secretary to the Agricultural Research Council.

Dr. Topley is one of the most distinguished of the British bacteriologists of recent years. The most important of Topley's contributions to bacteriology and experimental medicine has been the experimental study of epidemics, which he initiated and of which the methods have been largely his own creation. Much had been learned by the statistical analysis of observational data, dealing with the origin, spread and development of natural epidemics, under conditions largely out of control. Topley conceived the idea of applying such methods to the investigation of epidemics started artificially in populations of healthy mice, kept in the laboratory under conditions which could be exactly controlled and deliberately varied. Thus the factors conducive to the rise, culmination and decline of an epidemic, to its revival or its final subsidence, could be experimentally determined. In a long series of such studies, the important results of which were reviewed in his Croonian Lecture for 1941 on "The Biology of Epidemics", Topley had the statistical co-operation of Prof. Major Greenwood, in both planning and interpretation.

On this firm basis of knowledge concerning the incidence and mortality of a naturally transmitted infection in untreated stock, the efficiency of prophylactic measures could be put to a controlled test. Under Topley's guidance and inspiration, accordingly, substantial progress has been made by his chemical colleagues towards the isolation from various species of pathogenic bacteria of highly purified and stable antigens, and the practical trial of some of these was interrupted by the outbreak of war.

Dr. Topley's researches have had a great and lasting influence on the study of bacteriology, immunology and epidemiology in relation to human medicine. His recent change of the focus of his interests may be expected to give an important stimulus to advance in many cognate fields of agricultural research.

Davy Medal

The Davy Medal has been awarded to Prof. C. N. Hinshelwood, Dr. Lee's professor of chemistry in the University of Oxford.

The award has been made for Prof. Hinshelwood's work on the kinetics of chemical change, characterized by its pioneering quality and by the varied new lines of research which it has opened up. An experimental investigator of great skill and achievement, Hinshelwood has also enlarged the theory of the subject by able mathematical analyses and descriptions based on the concepts of collisions and of activation energy.

Hinshelwood took a leading part in the early study of homogeneous gaseous reactions. As the result of the examination of a number of bimolecular examples, he was able to show, with reason, that these are confined to molecules containing few atoms, and that the actual rate was given by the product of the total collision rate and the probability of a molecule possessing the experimental energy of activation. Unimolecular reactions were found to occur with polyatomic molecules and to show more complex features. In association with Prof. F. A. Lindemann (Lord Cherwell), Hinshelwood put forward the mechanism, now accepted, whereby a reaction fundamentally dependent on collisions may nevertheless have unimolecular kinetics. This theory he was able to verify by showing that the rates of such reactions diminish at low pressures and that the kinetics then become bimolecular.

In the field of chain reactions Hinshelwood opened up new lines of advance by studying the therma reaction between hydrogen and oxygen. Thus he discovered, and offered clear explanations for, the curious phenomenon of 'explosion limits', confining explosive reaction, at any fixed temperature, sharply to a particular pressure region. Elaborate studies on the effects of nitrogen peroxide and other foreign gases on the hydrogen–oxygen reaction brought to light the very great kinetic complexities of an apparently simple type of chemical change. In this work Hinshelwood directed attention to the influence of the container surfaces on chain reactions, and also clarified the confusion of evidence concerning the effects on reaction rates of the intensive drying o gases. His discovered the inhibition of certain gaseous reactions by nitric oxide and interpreted the effec as due to the removal of radicals from, and the suppression of, 'chains'.

Hinshelwood has also carried out a large number of experiments on heterogeneous reactions and shown that their differences in kinetic behaviour can be explained by the application of the concepts of Langmuir.

Throughout all these researches, carried out with the utmost economy and directness, though with full experimental precautions, and interpreted in the mos lucid manner, Hinshelwood has never lost sight of the essential complexity of chemical reaction mechanisms. He has always been ready to modify his views in accordance with new experimental evidence, and to make the fullest use of the more recent developments of wave-mechanics and of statistical mechanics. Summarized by their author in two well-known treatises, Prof. Hinshelwood's distinguished researches furnish abundant ground for the award to him of the Davy Medal.

Darwin Medal

The Darwin Medal has been awarded to Prof D. M. S. Watson, Jodrell professor of zoology and comparative anatomy at University College in the University of London.

Prof. Watson is pre-eminent among palæontologists for his contributions to knowledge of the course of vertebrate evolution. His researches have been concerned mostly with the origin of the land vertebrates, with the fishes most nearly related to them, and with the main line of evolution leading to the mammals.

It will not be possible to survey here Watson's work in all its aspects, and mention must be restricted to some of the major lines of advance which it has opened. His Croonian Lecture, in 1925, summarized the conclusions which he had reached by that date as to the evolution of the Amphibia, demonstrating for the first time the relationship of the Stegocephalia to the Osteolepid fishes. In addition to tracing the descent of land vertebrates thus from Amphibia back to fishes, Watson followed the line of the evolution of the mammals, through early, primitive reptiles, the Cotylosaurs, to the mammal-like reptiles, in a large series of valuable papers. He related this work on the reptiles to that on the amphibians in a paper on the evolution of the shoulder girdle of the Tetrapoda

In this work on the fossil vertebrates, in its relation to the course of evolution, Watson has not confined his attention to morphological details, but, with an enterprise remarkable in a palæontologist though characteristic of his outlook, has considered where possible the functional significance of the structures preserved in the rocks; thus he has considered the mode of action of the shoulder girdle and deduced the nature of the musculature of a group of marine fossil reptiles.

Pursuing his study of mammalian origins, Watson was led to study the most primitive of living mammals, the oviparous Monotremes, and to discover that characters in which their skulls differ from those of other mammals can be regarded as extreme developments of features observed in the skulls of certain fossil, mammal-like reptiles.

Watson's work has continued in full vigour into recent years, and has brought two further contributions of major importance to the study of evolution in the vertebrates. One is concerned with the origin of the frogs from more primitive amphibian types, while the other shows that a group of fishes from the Old Red Sandstone constitutes a separate class of vertebrates, equal in rank to and ancestral to the remaining fishes.

Tracing, in this brilliant series of researches, the main stages of the descent of the mammals from their earliest fish-like ancestry, Prof. Watson has certainly performed "work of acknowledged distinction in the field in which Charles Darwin himself laboured".

Buchanan Medal

The Buchanan Medal has been awarded to Sir Wilson Jameson, formerly dean of the London School of Hygiene and Tropical Medicine and since 1940 the chief medical officer to the Ministry of Health and the Board of Education.

In both capacities Jameson has shown himself to be a man of stimulating influence and leadership, determined and persistent in his efforts to ensure that advances of medical knowledge in the laboratory, the clinic and the field shall receive prompt application n administrative practice.

Largely to Jameson's vigorous policy is due the hope that active immunization against diphtheria, which has banished the disease from many large communities of North America, will at length find systematic and effective application in Great Britain, where many of the discoveries were made which have rendered it safe and practicable. In the prompt official adoption of methods using modern technical resources to deal with the recent increase of tuberculosis under war conditions, and in the recognition of adequate and scientifically planned nutrition of the people as a central item of an effective health policy, Jameson's active and enlightened influence can again be discerned.

Of the grounds on which the founder of the Buchanan Medal desired the awards of it to be made, Sir Wilson Jameson's high claim to it is based on 'administrative and constructive work" of outstanding merit in the service of hygienic science.

Hughes Medal

The Hughes Medal has been awarded to Prof. Enrico Fermi, now of New York.

Prof. Fermi has made most notable contributions both to theoretical and experimental physics. In the early days of the modern quantum theory he was one of the first theoretical physicists to appreciate the generality of the considerations put forward by Pauli and known as the 'exclusion principle'. This led him to discuss the statistical theory of a perfect gas of particles in equilibrium, obeying this principle, with results which were obtained independently and almost simultaneously by Dirac by similar methods. These results of Fermi and Dirac are of the utmost importance in the modern theory of assemblies of similar particles, such as electrons, protons, and neutrons. Following this outstanding personal contribution, Fermi played a great part in building up at Rome a distinguished school of theoretical physics, where he himself made one of the earliest successful attempts to construct a theory of radioactive β-ray change. This theory shows the most profound insight into the theoretical nature of the quantum theory.

His interest in the atomic nucleus led Fermi naturally to his experimental studies in this field. Immediately after the discovery of the neutron, he realized that it provided a new possibility of attack on the nucleus and of stimulating nuclear change by neutron bombardment. This work opened up the fruitful modern field of study concerned with the transformations of nuclei of medium and great atomic number, and led directly to the most exciting transformations of all, the nuclear fission of uranium and thorium.

Prof. Fermi's work is characterized throughout by profound insight and great experimental skill. In the fields which he has made his own he is universally acclaimed a leader.

ANALYSIS AND TESTING OF COAL

THE testing of coals for their suitability in use, even after many years of effort, continues to give rise to investigation. This is due to the great economic importance of fuels, change in methods of utilization, and also to the fundamental complexity of the nature of coal. Unlike many raw materials, every coal contains several constituents, recognizably distinct, which vary in composition and character according to their origin and geological age. Moreover, they contain inorganic matter which varies widely in chemical composition and physical properties.

These complexities make the actual chemical composition of secondary importance, with the possible exception of the sulphur content. The so-called 'proximate analysis' is of prime importance as a guide to the usefulness of a coal. This involves the measurement of the quantity of combustible and of incombustible matter. Each is further subdivided —the combustible into 'fixed' carbon and volatile matter, the incombustible into 'ash' and 'moisture'. By means of these empirical tests, the observant and experienced analyst can reach useful conclusions as to the suitability or unsuitability of a coal for many purposes. Standardization of such a test is essential and more than forty years ago the American Chemical Society drew up a standard procedure. A few years later the United States Bureau of Mines made a start on this work, which has been continued in other industrial countries until a vast literature has been collected.

Dr. A. C. Fieldner, chief of Fuels and Explosives Services, U.S. Bureau of Mines, in his Melchett Lecture to the Institute of Fuel, delivered by talking film on October 13, traced the development of testing methods in the United States. It was early found that the kind and quantity of inorganic constituents greatly influenced the serviceability of a coal. Fieldner himself was closely associated with the necessary tests. As time went on, further specialized tests have been developed—a work in which British chemists have largely participated, particularly in association with the British Standards Institution. Only recently the Institution has issued a new edition of British standard methods for the sampling and analysis of coal. It reveals a noticeable increase in the elaboration of method, even in regard to the simple 'proximate analysis'. This is doubtless due to the fact that the simplicity is more apparent than real, and the complexity of coals provides many pitfalls.

The wisdom of over-elaborating the apparatus and method of the 'proximate analysis' is open to question. There is a place—the largest place—for a test in which a crucible is heated over a Bunsen burner. If a greater precision is required, it is possible that a more precise test than that now prescribed is preferable. Time has brought more and more specialized tests, designed to judge the suitability of a fuel for defined applications, for example producers, hand- or machine-fired, mechanical stokers, carbonization processes. War-time conditions have emphasized the need for these. In peace-time, coals tended to gravitate into appropriate channels, which war-time difficulties have choked or diverted. This has forced some industries to give thought to the more exact determination of their needs in order to secure that substitutes shall be really effective. All this has emphasized the importance of the subject of coal testing.

H. J. Hodsman.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Saturday, December 5

Society of Chemical Industry (Yorkshire Section) (in the Hotel Metropole, Leeds), at 2.30 p.m.—Dr. G. W. Scott Blair: "Some Rheological Problems in Industry".

Saturday, December 5—Sunday, December 6

Association of Scientific Workers (with the support of the British Association) (at Gas Industry House, 1 Grosvenor Place, London, S.W.1)—Conference on "Scientists of the United Nations and the War Effort".*

Saturday

At 2.30 p.m.—"Allied Scientists" (Chairman: Sir Richard Gregory, Bart., F.R.S.).

Sunday

At 11 a.m.—"Free National and Refugee Scientists" (Chairman: Prof. John Marrack).

At 2.30 p.m.—"British Scientists" (Chairman: Sir John Russell, F.R.S.).

Monday, December 7

Society of Chemical Industry (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. W. D. Jones: "Powder Metallurgy".

Royal Geographical Society (at Kensington Gore, London, S.W.7), at 5 p.m.—Dr. L. Dudley Stamp: "The Scott Report on Land Utilization in Rural Areas".

Tuesday, December 8

Chadwick Public Lecture (at the Royal Society of Tropical Medicine and Hygiene, 26 Portland Place, London, W.1), at 2.30 p.m.—Dr. W. Norwood East: "The Differentiation, Prevention and Treatment of Anti-Social Behaviour Disorders".*

Royal Institution (at 21 Albemarle Street, London, W.1), at 3 p.m.—Prof. J. C. Drummond: "The History of our More Important Foods", (iii) Dairy Produce.*

Illuminating Engineering Society (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 5 p.m.—Discussion on "Lighting and Post-War Reconstruction (Guidance, Specification and Legislation)", to be opened by Mr. A. G. Higgins.

Wednesday, December 9

Royal Society of Arts (at John Adam Street, Adelphi, London W.C.2), at 1.45 p.m.—Dr. George Yeh: "The Cultural Life of War time China".

Physical Society (in the Cavendish Laboratory, Cambridge), a 2.30 p.m.—Prof. E. N. da C. Andrade, F.R.S.: A lecture on Newto (in celebration of the Tercentenary of Newton's Birth).

Institute of Physics (in the Lecture Theatre of the Royal Institution, Albemarle Street, Piccadilly, London, W.1), at 5 p.m.—T celebrate the Three-hundredth Anniversary of the birth of Sir Isaa Newton. Dr. H. Lowery: "Life of Newton"; Dr. H. F. Buckley "Some Historical Aspects of Newton's Published Works".

Thursday, December 10

Institute of Fuel (at the Connaught Rooms, Great Queen Stree Kingsway, London, W.C.2), at 2.30 p.m.—Mr. H. E. Partridge "Fuel Economy at Collieries".

Pharmaceutical Society (at Friends House, Euston Road London, N.W.1), at 2.30 p.m.—Dr. R. Melville: "Medicinal Indigenous Plants".

Friday, December 11

Royal Society of Arts (India and Burma Section) (at Joh Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Kahn Bahadu Sir Azizul Hugue: "Rural Self-Governing Bodies in India".

Physical Society (Colour Group) (at the Lighting Service Burea of the E.L.M.A., 2 Savoy Hill, Strand, London, W.C.2), at 2.30 p.m —Dr. John W. Strange: "Fluorescent Materials and their Colours" Mr. G. T. Winch: "The Photometry and Colorimetry of Fluorescen Lamps"; Mr. H. G. Jenkins: "Commercially Useful Fluorescen Substances"; Mr. F. W. Coppin: "The Use of Fluorescent Pigment in Colour Printing".

Royal Institution (at 21 Albemarle Street, London, W.1), a 5 p.m.—Mr. E. R. Davies: "The Photographic Analysis of Motion'

Saturday, December 12

British Mycological Society (at the Linnean Society, Burlingto House, Piccadilly, London, W.1), at 2 p.m.—Miss E. M. Blackwell "On Germinating the Oospores of *Photophthora cactorum*" (Presidential Address).

Free German Institute of Science and Learning (at 16 Buckland Crescent, Hampstead, London, N.W.3), at 5 p.m.—Prof. M Polanyi: "The Scientific Community".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Dairy Bacteriologist for the London Area—Th Acting Principal, The College, Wye, Ashford, Kent (December 8).

Lecturer in Biology—The Registrar, Technical College, Sunderland, Co. Durham (December 11).

Lecturer in Physical Chemistry—The Registrar, The Universit Bristol (December 12).

Instructor in Beekeeping—The Education Officer, County Hal Wakefield (December 14).

Lecturer in charge of Mining at the St. Helens Municipa Technical College—The Director of Education, Education Offic Cotham Street, St. Helens (December 14).

Head of the Department of Science and Technology, an Head of the Commerce Department, of the Southend-on-Sea Municipal College—The Chief Education Officer, Education Office, Warric Square, Southend-on-Sea (December 18).

Headmaster of the King Edward VI Grammar School—Mr. John Hales, Clerk to the Governors, The Close, Norwich (December 18).

Assistant Lecturer and Demonstrator in Botany—Th Secretary, West of Scotland Agricultural College, 6 Blythswood Squar Glasgow (December 28).

Regius Professor of Geology at Edinburgh University—Th Private Secretary, Scottish Office, Fielden House, 10 Great Colleg Street, London, S.W.1 (January 11).

Assistant Master with good qualifications in Mathematic and Engineering, and an Assistant Master (or Mistress) to tak Geography and General Science—The Principal, Technical Institute,, Gravesend.

Assistant (male or female) to the Public Analyst—The Secretary, Health Department, Grey Friars, Leicester.

Veterinary Investigation Officer—The Principal, Universit College of Wales, Aberystwyth.

Physics Instructor in a leading Technical College in Chile—Th British Council, 3 Hanover Street, London, W.1 (endorsed 'Chile').

Physics Master, and a Chemistry Master, in the Victoria Colleg Alexandria—The British Council, 3 Hanover Street, London, W. (endorsed 'Alexandria').

Research Assistant (male) with Zoological or Agricultura Qualifications to work on Pest Control—Wood Pigeon Investigation, Edward Grey Institute, 39 Museum Road, Oxford.

Assistant Analyst—The Medical Director, Evans Biologic Institute, Runcorn, Cheshire.

Laboratory Attendant—The Laboratory Superintendent, Department of Chemistry, Imperial College of Science and Technolog South Kensington, London, S.W.7.

RELATION OF CO-OPERATION TO MORALE

THE increasing stringency of the labour position and the ever more searching demands upon the man-power and woman-power of Great Britain are steadily driving home the lesson that the central problem in efficient production is that of securing effective co-operation. That problem is encountered in the munition factories, in the shipyards and in transport; it is the dominant factor in solving the important problem of absenteeism. The true secret of the high production-levels of 1940 lies less in the long hours worked than in the spirit of the workers. The whole nation had been lifted to a level which made for effective co-operation and high morale.

To maintain morale and co-operation at that high level throughout the course of a long war is no easy task, but it is the key to victory. Without it we are likely to relax, and jeopardize all the harvest that now promises to be reaped from the African campaigns and the months of planning, vigil and training that made their success possible. Primarily, that is a responsibility of management, as the Select Committee on National Expenditure has rightly insisted, that term being understood to include the production departments of the Government and not of the industrialist alone.

As Prof. Elton Mayo points out in his foreword to Prof. F. J. Roethlisberger's recent book "Management and Morale"*, we must first of all recognize that whereas material efficiency has been increasing for two hundred years, the human capacity for working together has in the same period continuously diminished. It is true that the desire for continuous and intimate association in work with others persists, but the very strength of this persistent desire retards rather than promotes effective co-operation. The relative isolation of small groups and their constant feeling of insecure tenure induce an attitude of suspicion or even hostility to other groups or, in industry, to management. This is the road by which we drift to what historians call stasis—the disintegration of a community into an infinity of mutually hostile sections. In war or in peace alike, chaos and downfall are the sure result.

Clearly we cannot leave collaboration in a society any longer to chance. Prof. Roethlisberger's volume, addressed primarily to business executives, is a study of what is involved in collaboration, and he indicates methods not in conflict with the democratic tradition which can be applied to the remedy of social and industrial disorders. He shows that collaboration is a field for serious study and research, and he should also stimulate much fruitful thought regarding the handling of certain problems of personnel in industry, perhaps more especially in regard to incentives and the very complex issues involved in absenteeism. In particular his book should lead to an attempt to aim our methods at the maintenance of co-operation and not merely at mechanical efficiency.

Prof. Roethlisberger starts from the Western Electric Company's researches at the Hawthorne Plant, which although they have been described in such books as Elton Mayo's "Human Problems of an Industrial Civilisation", T. N. Whitehead's "The Industrial Worker" and "Statistical Studies in Industrial Research", are still far from being as widely known as they deserve. These researches demonstrated that the responses of workers to what was happening about them depended on the significance those events had for them. His book, in fact, is an essay on human situations in business; it examines the hypothesis developed in these researches, uses their method to explore the complex human relations in a business organization and suggests the conditions for effective collaboration.

Industry, it is urged, is a social as well as an economic phenomenon, and leadership should be based on understanding as a prerequisite. The social structure of any particular company determines the kind of collaboration, the kind of people who will stay in the company, and the kind of people who will reach the top—an observation which is highly pertinent in considering the proposals in regard to the post-war structure of industry and trade recently advanced by a group of a hundred and twenty industrialists in Great Britain. Many industrial problems clearly need re-definition in terms of social structure; it is a fallacy to assume that with an intelligent understanding of the conditions necessary for getting raw materials and the technical production and distribution of goods, we need give little attention to the problems involved in co-operative effort.

The War at least has taught us that we cannot safely assume that the human problems of effective and purposeful association in work can be left to take care of themselves. Fundamentally, indeed, it might well be argued that the problem of civilian morale in war-time is that of so integrating individual and group activities with the national needs and purpose, that there is the maximum satisfaction of individual and of group and national demands. Obviously that objective cannot permit the misunderstanding or friction which will arise if a particular economic activity is torn apart from its social fabric and treated as a thing in itself. Neither can management continue to subsume the problems of group collaboration under the technical problems of production and efficiency. The social, as well as the physical, structure of an industrial concern must be considered, and regard had to the effect of a technical change introduced by the management on the social as well as the physical location of the individuals and groups of which modern industry is built up. Above all, there must be explicit understanding by the management of the social structure of industry, and effective communication up and down the line as well as between the different groups within the industry.

The importance of communication cannot easily be overstressed. Prof. Roethlisberger's chapter on "Words and Men" deals a shrewd blow at the jargon in which inefficiency and muddle so often attempt to clothe themselves. If communication and collaboration between groups in industry are to be effective, it is as important, if not more important, for management at the top to understand and appreciate the behaviour of the people at the bottom level, as it is for the bottom group to understand the logical and economic objectives. On that truth rests the whole case, in the larger sphere of world affairs, for a statement of war aims, and Sir Stafford Cripps's recent speech to the International Youth Conference in London went far to show that this is at last being appreciated by the Government. The situations and sentiments of individuals and groups which make up an organization, a society or a nation must be understood by its leaders before they practise the art of persuasion or assurances to secure loyalty, confidence and co-operation.

The importance of personnel management was stressed in the latest report of the Chief Inspector of Factories. Accepting the fundamental conception of industry as a problem of personnel as well as an economic phenomenon, Prof. Roethlisberger shows that the first human problem in a business concern is to secure the co-operation of people in attaining its collective purpose. The problem has three major aspects: first, relating to the channels of communication within the organization through which employees can learn about their duties and obligations in relation to its purpose, and express their feelings and sentiments about their methods and conditions of work; secondly, maintaining a social balance within the organization so that employees by contributing their services are able to satisfy their desires and hence are willing to co-operate; and thirdly, effecting the individual adjustments required to assist particular employees with difficulties to become better oriented to their situations.

These human problems are not simple or easy to solve, but they must be faced in any efficient industrial organization; and until they are faced and solved generally, our war effort will lack something of its full power. That much is clear from the reports of the Select Committee on National Expenditure and of the Chief Inspector of Factories. What is equally important but by no means so fully appreciated is that if we neglect them we may well lose the peace The human problems are indeed the crux in planning for the future. No planning which fails to take account of them is likely to be effective. Whereas it is important to have the machinery of planning established and the broad lines of policy determined in readiness, it is equally important that the purposes and objectives of that planning should be made known so as to secure the measure of co-operation that will be indispensable to success.

It is the great merit of democracy that its methods and traditions promote the solution of this problem of maintaining under given conditions the type and kind of equilibrium which make for the maximum efficiency and collaboration. Much of the mischie of the past thirty years has come, as Prof. Ernest Barker shows in his prescient "Reflections on Government", from our disregard of the democratic process Prof. Roethlisberger's study tends to support the view that friction and failure in business enterprise is due to the absence or imperfect development o those methods of open discussion and voluntary agreement which characterize the democratic State.

There is no distinction between the problems of morale in an industrial organization and those in any other organization or society. There are the daily problems of maintaining internal equilibrium, that is, of maintaining the kind of social organization in which individuals and groups working together can obtain human satisfactions that will make them willing to contribute their services to the economic objective of co-operation. There are the daily problems of diagnosing possible sources of interference, liquidating human tensions and strains among individuals and groups, helping people to orient themselves to their work groups, and detecting blockages in the channels of communications. These indeed are the very problems which tend to be overlooked, at least outside of the Armed Forces, under the stress of war, and without leaders skilled in diagnosing human situations we cannot preserve the social values which are so essential in a co-operative system. Prof. Roethlisberger's book, with all its suggestiveness and practical hints, is by and large another exposition of the truth of the ancient proverb, "Where there is no wisdom the people perish". Nothing could more surely hasten the day of full victory than leadership which, from top to bottom, handled the human problems of production and organization—and reconstruction—with understanding, imaginative insight, and the same courage which marked the finest hours of the summer and autumn of 1940.

COSMOGONY AND RELIGION

The Beginning and End of the World

Riddell Memorial Lectures, Fourteenth Series, delivered before the University of Durham at King's College, Newcastle-upon-Tyne, in February 1942. By Prof. Edmund Taylor Whittaker. Pp. 64. (London: Oxford University Press, 1942.) 2*s*. 6*d*. net.

EVERY year the Riddell Trust arranges for a course of lectures on "the relation between religion and contemporary development of thought". The Lectures for 1942 deal particularly with the relation between cosmogony and religion, and it is a matter for congratulation that the trustees have found a lecturer who is well-versed in both science and theology.

The greater part of the book consists of an exposition of the findings of astronomy and physics as to the beginnings and endings of the universe. This is admirably done, and would suffice by itself to make the book one of outstanding merit. Yet most readers will be mainly interested to see what Prof. Whittaker has to say on its religious implications. He tells us that the purpose of his lectures is to maintain the doctrine "that God, the first cause and last end of all things, can, from created things, be known with certainty by the natural light of human reason". From the evidence of science that the world is of finite duration in time, he deduces an argument against pantheism —if God were Nature and Nature God, then it would be necessary for God to be born and perish, which is absurd.

Apart from this, there is no sustained effort to discover God "from created things", or through any form of science. Whittaker holds that the influence of science on religion must be psychological rather than logical—new developments in science can never alter the Christian faith, but only man's receptivity to that faith. Here he is, of course, thinking of the immutable cast-iron faith of the Roman Church, rather than of the plastic faith of the liberal Anglican. This latter has often changed its shape (in so far as it has any shape) through the impact of new scientific truth—as, for example, through the recognition that our earth is not the physical centre of the universe, but a fragment which has become detached from a grain of sand in that vast swirling sand-storm we call space. With this in his mind, can the enlightened churchman of to-day be expected to hold, with his pre-Copernican ancestors, that the revelation to Moses on the mountain, or the birth of the Holy Child, were events of cosmical importance? Or, with Whittaker, that the Incarnation gave to this small planet the value of the universe, and to a narrow span of time the value of eternity? We wish that Prof. Whittaker could have discussed such questions, but he debars himself from so doing at the outset.

The reflection that "mankind appears for a brief space of time, a short instant in the duration of the stellar system, and then disappears" brings him to the age-old question: "Can the grand sum total of existence be so utterly futile as that?" To this he replies that in the copepods, which exist in countless billions in the sea, the individual counts for nothing and the race is everything, but that when we come to man the race loses its importance and the individual life acquires the supreme value. "The goal of the whole process of evolution, the justification of creation, is the existence of human personality." But this, as Whittaker agrees, is a matter of "what it is reasonable to believe", and not of what science encourages us to believe. Species after species lived on earth for many millions of years before extermination befell it; there can be no scientific warrant for supposing that man, who has not yet survived his first million years, and seems already to be making a fair mess of things, is the final culmination of creation.

The plain fact seems to be that cosmogony has disappointingly little to say on religion. The two never make real contact, still less come to grips—how could they? "The things that are seen are temporal, but the things that are not seen are eternal." Cosmology may confirm the first half of the Apostle's dictum, but provides too narrow a platform for the discussion of the second half. Science can speak with philosophy, and philosophy with religion, but attempts to short-circuit philosophy have usually failed, and perhaps must always fail; the universe does not carry its secrets written on its sleeve.

J. H. JEANS.

BRADLEY'S DIALECTIC

Bradley's Dialectic

By Dr. Ralph Withington Church. Pp. 189. (London: George Allen and Unwin, Ltd., 1942.) 10*s*. 6*d*. net.

THERE is real satisfaction for a lifelong student of philosophy, when he finds the loyalties of his youth emerging from obloquy and arresting the attention of a generation whose temper of mind is inevitably alien to his own. It is thus at the present time with Bradley. As Hegel said, it is a tribute to the greatness of a philosopher that he compels his successors to refute him. During the half-century that has passed since Bradley dazzled the academic world into submission by "Appearance and Reality", a host of critics, mostly hostile and destructive—Moore, Cook Wilson, Russell, Broad, Alexander and Whitehead—have done their damnedest, until it had become almost a *cliché* with younger thinkers to dismiss Bradley as a back number in metaphysics. They were tired of monism and the absolute and of idealist epistemology in general. Yet Bradley is still a living force, and now even the youngest, disillusioned with the new gods, are beginning to be interested in discovering for themselves what it was he had to say. Indeed, the two greatest in the above-mentioned list, Alexander and Whitehead, frankly confessed their indebtedness to Bradley's teaching; and have thereby contributed not a little to stimulate this revival of interest. The book before us, like Prof. Blanshard's more elaborate work "The Nature of Thought", bears witness to its vigour in the United States.

Dr. Church, who has already written on Hume and Malebranche, here devotes himself to the task of expounding the principles of Bradley's metaphysics. With his views on ethics and religion—perhaps the most valuable and suggestive facets of his thought for the present-day reader—he is wholly unconcerned. He is a purist, out for the rigour of the game, and keeps his eyes steadily fixed on questions of logic and metaphysics. These, for Bradley as for Hegel, stand or fall together as a single inquiry. In logic the crucial issue is that of the meaning to be attached to the principles of identity and contradiction. Henry Sidgwick once remarked, apropos of Hegel, that he could never make out when a contradiction was just a contradiction or when, on the other hand, it veiled a sublime truth. With the abstract formulation of these principles, A is A and A is not not $-A$, cherished by contemporary logisticians, Bradley will tolerate no compromise. It leads to the apotheosis of tautology, and for him tautology is the very negation of thought. Contradictories, he holds, mean contraries, so that between them a way lies open for a process of mediation. To present the law of contradiction in the form that contradictorily opposed propositions cannot both be true is to offer a circular definition; for it assumes that we already know what contradictory opposition is.

What Bradley means by contradiction is admirably expounded by Dr. Church in his seventh chapter (one of the best in the book), entitled "Identity in Difference". He means the assertion of a bare conjunction of unrelated characteristics. "To unite without an internal ground of connection and distinction is to strive to bring together barely in the same point, and that is self-contradiction" (117). In other words, and here the logical doctrine appears in the foundation stone of Bradley's metaphysics, all identity is relational and implies qualitative difference. That is why, following Bradley's own lead (7,15), Dr. Church opens with a detailed analysis of his argument in the too-much neglected chapter (6) on "Relation and Quality" in Part I of "Appearance and Reality". To this argument he returns again and again, with perhaps excessive reiteration, throughout the book; for all Bradley's metaphysical doctrines, his monism, his absolutism, his theory of degrees of truth and reality, as well as the logic of contrariety, are based upon it. The point of the denials that relations are merely internal or merely external is clearly brought out, with special reference to Dr. Ewing's ten possible meanings in which the phrase "internal relations" can be understood. Free use is made not only of Bradley's *magnum opus*, but also of his important posthumous notes for an essay on "Relations".

That Dr. Church quotes Bradley's own words frequently is fortunate for the reader, for his own style in commentary and elucidation is by no means free from obscurity. In fact, we are constantly reminded how Bradley, like God in the well-known hymn, is "his own interpreter, and he will make it plain". One further ground of criticism is Dr. Church's use, in expounding the principle of identity in difference, of the phrase, "concrete universal". What is meant is, of course, a systematic whole of differents; but such an entity is not a universal at all, but an individual. The phrase, of course, is ever on the lips of Hegel and of Hegel's followers; but seldom has an important speculative truth been sponsored under such an ill-omened name.

In the penultimate chapter (7) Dr. Church discusses certain "basic difficulties" that stand in the way of a wholehearted acceptance of Bradley's metaphysic. For one thing, there is the denial of any merely numerical differences in quality, a denial that is in accord with the whole trend of Bradley's argument. It does not admit of demonstration, either *a priori* or by induction. But, the author points out, the assumption "is not made arbitrarily" but forced on Bradley by experience. Experience is a process of becoming, and qualities and relations that differed *solo numero* would be self-identical and unchanging, and "could not be moments in any process of becoming" (149). Moreover, there is the crowning obstacle that since the absolute can stand in no relations, "we are left at the close with no criterion of degrees of truth or reality" (157). Degree of coherence is an index to degrees of intellectual satisfaction. But can we assert the converse, that "the fuller the satisfaction, the higher the coherence"? Surely not so; and we are left, owing to our restricted knowledge of the absolute, without "an index of degrees of coherence" (159–160). It looks, therefore, as though Bradley's absolutist metaphysics rested, not only at the start but also at the close, on what can scarcely be otherwise described than an act of faith.

W. G. DE BURGH.

READINGS IN THE HISTORY OF BOTANY

A Short History of the Plant Sciences

By Prof. Howard S. Reed. (A New Series of Plant Science Books, Vol. 7.) Pp. x+320. (Waltham, Mass.: The Chronica Botanica Co.; London: William Dawson and Sons, Ltd., 1942.) 5 dollars.

AN author who does not write a book to order chooses his own subject matter and has a perfect right to do so. In making his choice he is guided by certain considerations of which his own particular interests are likely to be among the more important. For this reason we cannot complain of the content of Prof. Reed's book. On the other hand we have every reason to feel aggrieved at the title he has selected, for it must give the prospective reader a very wrong idea of what he will find between its covers. For what are we to think of a history of the plant sciences which deliberately excludes any account of the development of plant genetics and fossil botany, or of systematic botany after the eighteenth and plant geography and ecology after the nineteenth centuries, and in which the only aspect of physiology considered is metabolism ?

About a third of the book, comprising the first seven chapters, consists of a statement of botanical and horticultural knowledge at different periods of the world's history, beginning with an account of the plant lore of the early civilizations of Assyria, Egypt, China and America and then proceeding from what the author calls the nascent period (sixth century B.C. to second century A.D.) to the seventeenth and eighteenth centuries. After an intercalated chapter on gardens, later work on a number of botanical topics is summarized in the remaining eleven chapters. The extraordinary lack of balance in the treatment of the subject is again evident here, for of these eleven chapters no less than six are devoted to certain aspects of metabolism, while plant geography, morphology, cytology, mycology, pathology, are restricted to one each.

In writing a history of any science it should surely be the aim of the historian to trace the development of the science in its various branches and to show how the discoveries made and theories held at any time have led to further discoveries. With this in mind, how is it possible to write a history of the plant sciences without an adequate account of the work of Charles Darwin ? For this work had a profound influence on the development, not only of genetics, but also of morphology, physiology and systematic botany, and it is clear from his Introduction that the author is fully aware of this. Yet in Prof. Reed's book the only observation of Darwin's which is described in detail is that on vacuoles in the tentacles of Drosera, and the reason why this selection should have been made is quite unclear.

Indeed, the whole book takes only too often the form of a series of abstracts of selected pieces of work by various investigators of greater or less distinction, but it is not always at all obvious on what principle the selection has been made. Thus no work on photosynthesis during the last fifty years has had a greater influence on the development of our knowledge of this subject than that of F. F. Blackman, yet in the chapter on the fixation of carbon by plants no account is given of this work, and Blackman's name does not even occur in the list of references at the end of the chapter.

From what has been written above it must not be concluded that the book is without interest. On the contrary, the author has here brought together much valuable information which is certainly not readily accessible to the majority of botanical students. This is particularly the case as regards the knowledge of plants and horticultural and agricultural practice in early times, and for this reason the first few chapters make interesting reading. But the author has wider aims than the provision of such matter. One of his intentions is "to guide students during the formative period to a better understanding of past and present trends and to clarify the increasingly complex situation into which they will eventually be thrust". But one wonders what a student "in the formative period" and without a training in Egyptology makes of references to the fifth, twelfth, eighteenth, twentieth and twenty-sixth dynasties without any indication as to when these flourished; and when he is told that the original habitat of the potato is a matter of paramount importance for many reasons, he would surely like to know these reasons, but he is not told. Again, can he make sense of the statement "there is evidence that he knew more about the matter than we suspect" ? This is, perhaps, only careless writing, and probably the same judgment can be made on the author's statement that he has "sought to give vitality to outstanding men".

But what of the following pronouncements from the first chapter ? "The study of the broader aspects of the plant sciences ought to orient the student and to counteract, to some extent, the effects of the inevitable specialization which modern scientific curricula impose upon him. The flood of technical papers which continually surges over the tables and into the bays of the libraries dismays the student who wishes to evaluate the progress of science. To say nothing of the cultural, there is also practical value in having some background for judging things pertaining to a field of science, if one is to avoid grasshopper habits of thinking." And again, "One must get a long view if he can distinguish the real direction of man's progress in botany among all the devious, puerile ways in which he squandered his time and energy. And let it be remembered that we of this day may be, and probably are, beating about the bush or chasing rabbits as assiduously as our predecessors."

Were it not that British and American literature in general proves the contrary one might be tempted to agree with Prof. Reed's compatriot who, in a recent broadcast, said "The British and the Americans are alike in that they both believe, wrongly, that they speak the same language". W. STILES.

THE CONTENT OF MATHEMATICS

What is Mathematics?

An Elementary Approach to Ideas and Methods. By Richard Courant and Herbert Robbins. Pp. xix+521. (London, New York and Toronto: Oxford University Press, 1941.) 25s. net.

THIS is a thoroughly good book which deserves to run through many editions. It is not (as its title might suggest) a book on mathematical logic or philosophy: it deals not with the *nature* of mathematics but with its *content*. Its purpose is to show, not by general disquisitions but by concrete examples, drawn from almost every branch of pure mathematics, how mathematicians think and what they do.

I know only three good books with similar aims: Whitehead's "Introduction to Mathematics" in the Home University series, Rademacher and Toeplitz's "Von Zahlen und Figuren", and Dresden's "An Invitation to Mathematics"; and Dresden's is the only one of the three which really challenges comparison. The other two books, excellent as they are, are slighter and much less systematic, and Whitehead's is written more from the point of view of a logician. It is odd that the best two books of the kind should both be American, but the public for which they are designed is no doubt largest in America.

The writing of such a book, for "beginners and scholars, students and teachers, philosophers and engineers", is a formidable task which requires an unusual combination of qualifications. The authors must be professional mathematicians, since no one else can have the reserves of knowledge and the mastery of technique which are essential; and with these professional qualities they must combine a breadth of interest and a literary skill which very few professionals possess. Finally, they must be *honest*, and set themselves resolutely against any attempt to catch an audience by making their subject cheap.

In this respect the attitude of the authors is irreproachable. They do not pretend that their book is all easy arm-chair reading, or is likely to have a wide vogue among "tired business men". They know very well that mathematics is a serious and sometimes an exacting discipline, and that anyone who wishes to master even a little of it must be prepared to face a certain number of uncomfortable hours. They have done their best to smooth the path, and on the whole with remarkable success; but they realize, and warn their readers honestly, that no one can learn anything worth knowing about mathematics unless he has "a certain intellectual maturity and a willingness to do some thinking on his own". Very little *knowledge* is required; no more than could be learnt from any good high-school course.

I can think of quite a number of classes of readers for whom the book is just adapted: really clever schoolboys of fifteen, freshmen undergraduates of average mathematical ability, secondary schoolmasters, university lecturers in physics and engineering, even a minority of philosophers. All of them (except the first) will find difficulties somewhere, but a book on mathematics without difficulties would be worthless. Finally, even professionals (though they will naturally skip a lot) will find the book well worth reading. Few of them will really know more than seventy per cent of the contents, and each will probably pick out for special praise the parts with which he is least familiar.

To me, for example, the best chapter is Chapter 5, on topology. Here are Euler's formula for polyhedra, the 'five colour theorem', Jordan's theorem (for polygons), Brouwer's 'fixed point theorem', and many suggestions of further developments. The proof of Brouwer's theorem, in particular, is a model of what a mathematical proof should be. Next I put Chapter 7 (on maxima and minima, with strong emphasis on the geometrical side): Schwarz's 'triangle problem', Steiner's 'road problem', the isoperimetric property of the circle, Bernoulli's investigation of the brachistochrone, and much other attractive matter. Here, on the fringes of the calculus of variations, Prof. Courant is naturally at his best as an expositor. It is a pity that the famous 'ham sandwich' problem should be a little too difficult to include: the two-dimensional analogue is solved in Chapter 6 as an application of Bolzano's theorem.

It is natural that I should find the arithmetical and analytical chapters less entertaining, but I have no serious fault to find with the authors' choice of material. There might perhaps be a little more about logic and 'fancy' algebras. The calculus comes late, in Chapter 8, but that I welcome: it will be good for 'practically minded' readers to learn that 'calculus for engineers' is nowhere near the centre of mathematics.

The chapter which I find the least satisfying is Chapter 4, on projective geometry, based as it is, like the accounts in the school-books, on ratios of lengths and other obviously metrical concepts. The geometers will agree with me, but the difficulty is fundamental, and I do not suggest that the authors are wrong in following (like Dresden before them) the course they take. The subject cannot be ignored but, treated really logically, in the manner of Veblen and Young or even of O'Hara and Ward, it becomes too bulky and formidable for a book like this. It is necessary to be rather illogical; but I think that the authors should have taken their readers a little further into their confidence, by the insertion of a few explanatory pages in which the difficulty is faced squarely. I would suggest this for the next edition: the explanations would demand great expository skill, but nothing which I should judge to be beyond the authors' powers.

I should add finally that the book is beautifully printed and the diagrams particularly well drawn.

G. H. HARDY.

ANALYSIS OF FOODS AND DRUGS

Aids to the Analysis of Foods and Drugs

By Dr. J. R. Nicholls. (Students' Aids Series.) Sixth edition. Pp. vii+424. (London: Baillière, Tindall and Cox, 1942.) 10*s*.

THE sixth edition of this well-known book requires no introduction, and it is a pleasure to note that Dr. Nicholls, who was responsible for so much good work in his revision of the previous edition, has now become the recognized author. This edition, which has been increased in size by about one third, contains several new sections; in addition, previously existing sections have been extended and revised. Many references to recent original work recorded in *The Analyst* and elsewhere have been included, and these alone make the book of great value to the practising analyst. The great majority of the new sections have been added to the chapters dealing with food; drugs now occupy only about a tenth of the book, an even smaller proportion than formerly. One might almost suggest that they could be omitted altogether; the book could then be removed from the "aids" series and published in more pretentious form as a text-book on food analysis.

Dairy products occupy the first hundred pages of the book. The statement, which has persisted from an early edition, that the total solids of genuine milk rarely fall below 12·2 per cent, would appear to require further explanation. The new section on vitamins deals briefly with each, giving the structural formulæ and references to the better established methods of assay; a short table at the end of the section gives the international unit and the sources of the better known. The appendix at the end of the book has been extended to cover the Food and Drugs Act 1938, and gives a short summary of the more important points likely to affect the food and drug analyst. A list is also appended of some of the more important regulations and orders governing food which have been passed since the War.

In his preface, the author perpetuates the statement originally made in the preface to the first edition, that the book is not intended as a cram book for the examination of the Institute of Chemistry in food and drugs. It might equally well be said that the student, if he uses the book as a guide and follows up the many references given, will find in it an excellent basis for the theoretical knowledge he requires.

J. H. SINGER.

Maps and Survey

By Arthur R. Hinks. Fourth edition. Pp. xiv+301+28 plates. (Cambridge: At the University Press, 1942.) 16*s*. net.

MANY of the older readers of NATURE will remember the thrills of excitement when the latest traveller returned to Great Britain with the story of some great discovery, but with a very meagre little map, as the secrets of the surface of the world were gradually unfolded. That epoch is now ended, but the art of surveying and of the making of maps continues to improve.

The issue of a fourth edition of Hinks's "Maps and Survey" is welcome, though, owing to military necessities, all the newer elements of military surveys cannot even be mentioned; Chapter 12, on photographic, including air, surveys, being left as it was nine years ago. The additions and corrections collected in Chapter 14 would have been more useful had they been printed on one side of the paper only, so that they could have been cut out and pasted on the appropriate page.

While the surveyor may learn to survey from Close's "Text-book of Topographical Surveying", his education would be incomplete without Hinks's book. The insoluble problem of the spelling of names is well treated, numerous difficult cases being quoted, notably that of the Grampians being called by the Russians Grampianski Gari, while we British in our turn are just as bad. The device mentioned on p. 47 of stamping typed names on to the drawing paper was the regular method employed by the Survey of India on all its maps except for engraved small-scale maps.

While methods of survey are rightly the preserve of the professional surveyor, the resultant map is essentially for map-users; the general public, therefore, is fully justified in making criticisms and suggestions as to the form, style and scales of maps they require. It is curious to read in these war days that it was the 1745 rebellion that made the British Government realize the need for accurate maps and was the cause of the inauguration of regular surveys in Great Britain. Even for a non-surveyor, this book, or at least the non-technical parts, is well worth reading.

What Price Alcohol?

A Practical Discussion of the Causes and Treatment of Alcoholism. By Dr. Robert S. Carroll. Pp. xv+362. (New York: The Macmillan Company, 1941.) 12*s*. 6*d*. net.

UNDER this somewhat unconventional title Dr. Robert S. Carroll, founder and medical director of the Highland Hospital, North Carolina, deals with the alcohol problem mainly from the psychiatrist's point of view. The book, which contains a preface by Dr. Adolf Meyer, emeritus professor of psychiatry at Johns Hopkins University, is divided into three sections entitled respectively "Why Alcohol?", "What Price Alcohol?" and "Alcohol or Man?" Recognizing as he does that there is no specific treatment for alcoholism owing to the great variety among the sufferers from this condition, the author advocates the elaborate study of each individual case, laying special stress on the importance of a daily association of the psychiatrist with the patient. He forecasts that the future progress of the campaign against alcoholism will be effected by an alliance of scientific searchers after truth and the avoidance of declamations against strong drink, while he suggests the creation of courses of mental hygiene for all types of schools and publicity sponsored by the State.

Other subjects discussed in this work are the biochemistry of alcohol, alcoholism in women, the relation of alcohol to sexual life, the treatment of benign cases and, most important of all, re-education. Drug treatment in the form of sedatives, morphia and its associates are regarded as unnecessary. The work is illustrated by the description of cases from the author's practice, some of which he has studied for fifty years.

The Life of Sir William Osler

By Harvey Cushing. Pp. xviii+1417+12 plates. (London, New York and Toronto: Oxford University Press, 1940.) 21*s*. net.

THE life of William Osler by Harvey Cushing, published in 1925, has held its place, and must continue to do so, as one of the greatest of medical biographies. The book under review consists of one volume instead of two, and contains, with unaltered text, only eleven of the forty-seven original illustrations. For these reasons it is less expensive than its forerunner and may well enjoy a wider circulation among medical students, to whose purses it is intended especially to appeal.

Cushing described his two volumes as a compilation of records put together in the hope that the story of Osler's life would tell itself through what he put on paper. Through this medium his personality, spirit and character were certainly revealed to the reader, but no attempt was made to appraise his professional accomplishments, considerable as they must prove to be when the final count is made.

Whether Drs. John F. Fulton and W. W. Francis, who are responsible for this new edition, will succeed in introducing it to as many students as they hope for may be in doubt. Even a single volume of nearly fourteen hundred closely printed pages is a formidable task to tackle, and yet another "Boswell" may one day abridge the text for another generation without decreasing its attraction and historical interest.

Both Osler and Cushing, who were intimate friends during twenty-five years, played prominent parts in the most productive era of clinical medicine in North America, the former by his unequalled personal charm and inspired leadership, the latter by his solid contributions to the advance of knowledge.

Allergy

Strangest of all Maladies. By Dr. Warren T. Vaughan. (Advancement of Science Series, No. 2.) Pp. 160. (London, New York and Melbourne: Hutchinson's Scientific and Technical Publications, 1942.) 10*s*. 6*d*. net.

THIS little book, as the subtitle states, is "a popular study of the causes and methods of treating asthma, hay fever, urticaria and other allergic diseases". Though primarily intended for the general reader, the work will be of service to many medical practitioners, who will be surprised by the author's interpretation of phenomena as allergic which they had previously attributed to some other cause. Examples of the kind are drowning and certain physical expressions of unrequited affection. The book is written in a humorous style, and the text is liberally interspersed by half-tones and line drawings of a correspondingly facetious character, which should facilitate the comprehension of so difficult a subject.

J. D. R.

TUBERCULOSIS IN PEACE AND WAR*

By Sir ARTHUR MacNALTY, K.C.B.

THE National Tuberculosis Service in Great Britain was established in 1912. This is an integral part of public health, and every measure calculated to promote the health and well-being of the community is a contribution towards it. It is a great machine of organization requiring constant overhauling, alterations and improvement. Thirty years have gone to the making of it, and these have not been unbroken years of peace.

Progress in the scheme's development was arrested by the outbreak of the War of 1914–18. War conditions associated with malnutrition or semi-starvation invite tuberculosis infection. Examples of high tuberculosis morbidity were seen in the enemy-occupied countries, and the present War is likely to show a similar incidence on an even more tragic scale. The disease is one of the camp followers of war.

The standardized death-rates per million living for pulmonary tuberculosis (England and Wales) rose from 988 in 1914 to 1,498 by 1918. Thereafter they fell. The main causes of this increase were contact infection, overcrowding, the breaking down of bodily resistance to infection through prolonged physical or mental strain, in some cases a lowered standard of nutrition and intercurrent infection, especially influenza. This is how tuberculosis spreads, and war conditions augment the rate of its progress.

My representations made in 1915 that military service would heighten the incidence of tuberculosis in the adult population, and that there would be an overwhelming demand for beds in sanatoria for ex-Service men and other workers, were justified after the War of 1914–18. The total number of ex-Service men invalided out of the Services on account of tuberculosis attributable to, or aggravated by, conditions of service, amounted, approximately, to 35,000, and provision had to be made for them as well as for civilians.

Great Britain had peace for twenty years, and in that period much was done to extend, improve and develop anti-tuberculosis work. Important features were:

(*a*) The surgical treatment of tuberculosis, including artificial pneumothorax, which has enabled successful treatment to be given to many intermediate and advanced cases of pulmonary tuberculosis, the arrest of whose disease was formerly regarded as either hopeless or problematical. It has also led to a more intelligent use of sanatorium and hospital treatment in relation to the individual patient.

(*b*) With this wider outlook and success in treatment should be associated the work done in tuberculosis by that great pioneer, Sir Pendrill Varrier-Jones.

(*c*) The improvement in X-ray technique and the consequent important aid afforded by X-rays in the diagnosis of pulmonary tuberculosis and in the control of collapse therapy.

(*d*) The close association of research work in tuberculosis with practical application.

(*e*) The Local Government Act of 1929, which made it possible to treat all necessitous cases of tuberculosis under the tuberculosis schemes of local authorities.

Let us look for a moment at the position in 1938, the last year of peaceful endeavour. All forms of tuberculosis were declining in our midst. In 1911 there were in England and Wales 38,422 deaths from pulmonary tuberculosis, a figure which in 1938 had declined to 21,930. The decline in deaths from other forms of tuberculosis was even more remarkable. In England and Wales in 1938 these deaths were 14,698; in 1938 they had fallen to 4,246. The prevention of contact infection, the increased pasteurization of milk, earlier ascertainment and skilled treatment, all no doubt had their effect in this remarkable result. It is bitter now to record that progress has for the second time in the history of the national tuberculosis scheme been retarded by the outbreak of a world war.

The baneful influence of war in favouring tuberculosis mortality is already revealed by the vital statistics of the present War. In 1939 the deaths from tuberculosis in England and Wales were 26,250. (War conditions only prevailed in a little more than three months of that year.) In 1940 they were 28,144 and in 1941 they had risen to 28,669. The increase would be greater if non-civilians were included. Comparing with the year from mid-1938 to mid-1939 as standard, the increase in deaths from respiratory tuberculosis amounted to about 6 per cent in the first year of war and 10 per cent in the second. Using the same standard of comparison, the increase in deaths from other forms of tuberculosis amounted to 2·4 per cent in the first year and 17·6 per cent in the second year. The bulk of this increase has been due to tuberculous meningitis; in the first half of 1940, deaths from this cause numbered 1,047, but in the first half of 1941 the total was 1,422, an increase of 375, while all other forms of non-respiratory tuberculosis showed a rise of only 41 (Stocks). For the first six months of 1942, deaths from all forms of tuberculosis were only 14,412 as compared with more than 16,000 deaths in the first half of 1941. This improvement has coincided with a lull in enemy attack.

In Wales alone no perceptible rise in deaths from tuberculosis was seen until the year 1941, and the total death-rates (tuberculosis, all forms) are lower than the death-rate for 1938. The population of Wales has increased while that of England has decreased by reason of war evacuation measures. The comparison must therefore be made with the greatest caution.

The death-rates from tuberculosis in Scotland per 100,000 were 70 in 1939, 82 in 1940 and 83 in 1941. The latter is the highest rate since 1932.

Through the courtesy of the director-generals of the Medical Services of the Royal Navy, Army and Royal Air Force, I am permitted to say that, as was anticipated, there has been an increase in tuberculosis in the Fighting Services since the outbreak of war. The incidence of pulmonary tuberculosis in the Army, so far as men are concerned, has shown no upward trend, and the incidence in the R.A.F. has been falling for the last six months. The increase noted does not mean that a healthy recruit is unduly exposed to contracting pulmonary tuberculosis. Service conditions may reactivate the disease or break down a poor resistance to the tubercle bacillus. With the introduction of conscription, tuberculosis in the Fighting Services is, as it were, a mirror picture of civilian tuberculosis. Furthermore, a Service man is under constant medical observation, and occult tuberculosis is more readily detected than in civilian life.

---

* Substance of the Malcolm Morris Memorial Chadwick Lecture delivered on November 24.

At the outbreak of war, there was a temporary dislocation of the tuberculosis services in some areas. There was a shortage of residential accommodation, for some of the sanatoria had to be converted into casualty hospitals, and in the excitement of war conditions, in many instances, advanced and infective patients were sent home contrary to the instructions of the Ministry of Health. The Ministry was able later in the year to release 6,000 beds for the treatment of tuberculosis. In 1940 patients were removed inland from hospitals and sanatoria in the eastern and southern coastal areas under the threat of enemy invasion. During the intensive bombing of London and other large cities, many tuberculosis wards in general hospitals were put out of action. All this has added to the difficulties of adequate residential accommodation, although, as the Minister of Health pointed out in June 1942, the main problem is the shortage of nurses for the tuberculosis service.

Evacuation and shelter life also provided their problems. Arrangements were made to meet evacuated persons' needs for continuation of treatment, and efforts have been made by medical supervision and attention to hygiene to diminish the risk of spread of infection in the shelters. Since the War, there has been an increase in tuberculosis mortality in mental hospitals and mental deficiency institutions.

Experts have pronounced that the present scale of rationing is adequate for the tuberculous, if carefully planned, as in sanatoria and hospitals. The consumptive at home or in lodgings may not be able to secure such a diet, and many think a case for special nourishment can be made out on these grounds.

War conditions are, for many reasons, favouring uberculosis among all callings. In this increased incidence the factory workers share, but the primary causes of it lie for the most part outside the factory.

Measures of prevention and treatment may be grouped into immediate and future measures. The deadly effects of tuberculous milk are well known, and universal heat treatment of all milk would abolish tuberculosis of bovine origin, which is responible for about 2,000 deaths in England and Wales annually as well as much suffering, illness, crippling and economic loss. Miniature or indirect radiography is an important aid to early diagnosis, but it reinforces and does not supplant clinical examination. It must not be used as a 'rule of thumb' diagnosis. Recent work in chemotherapy encourages the hope that ventually a drug may be found which will destroy he tubercle bacillus in man (*vide* "Chemotherapy and Tuberculosis", NATURE, October 31, p. 517).

After the War, Great Britain will be faced with a greatly increased incidence of tuberculosis, paricularly in ex-Service men. It is high time to marshall all our forces, and the Ministry of Health is already taking active steps. More institutional provision and beds will be needed. The village settlement, which provides the ideal solution of the tuberculosis problem, and other methods of rehabilitation will be required. The Medical Research Council favours the setting up f a national board in order to co-ordinate the planning of a national rehabilitation scheme. This was first advocated by Sir Pendrill Varrier-Jones in 936. The work and direction of such a board is called for especially at the present time.

MATHEMATICS IN THE U.S.S.R.

By PROF. IVAN VINOGRADOV

Moscow (by cable)

THE development of the science of mathematics in Russia is comparatively recent, beginning with the establishment of the Russian Academy of Sciences in the eighteenth century, when Bernoulli and Euler, leading mathematicians of the time, were invited to Russia. These men, however, remained foreigners, and did not create what may rightly be termed a Russian school of mathematics. Lobachevsky was the outstanding Russian mathematician, and he first propounded theories of non-Euclidean geometry, but he did not found a school of mathematics, and his ideas were not taken up by any pupils.

The real foundation of a Russian school of mathematics dates only from the latter half of last century, beginning with the work of Chebychev. Russian mathematics began at once to develop on three separate lines: the theory of numbers; the theory of probability; and the theory of approximation, the latter owing its origin to Chebyshev himself. Following on the heels of Chebyshev came a whole generation of brilliant mathematicians, among whom were Zolotaryov, Korkin, Markov, Voronoy, Lyapunov, and Steklov, whose work was in the main on the theory of numbers, the theory of probability and analysis. It was thus a characteristic of the Russian school of mathematics that its members were engaged mainly on the solution of practical mathematical problems, and generalized theories were built up on the basis of the investigation of concrete problems.

This tradition of concreteness and at the same time great profundity of investigation dates back to the time of Lomonosov, and has marked most of the work of Russian scientific men. Their research work did not follow the lines of existing scientific knowledge, but broke new ground for itself.

Shortly before the Revolution in Russia, mathematics branched out in a new direction, basing itself on the work of French mathematicians and dealing with the more abstract theory of analysis. The founders of this school were Luzin and Yegorov, after whom came a number of their brilliant pupils.

Since the Revolution the development of mathematics has been particularly successful, and Russian mathematicians have taken their place in the front rank in diverse realms of mathematical science. The first place is occupied by the theory of numbers, which, thanks to the work of Chebyshev, Markov, Voronoy and others, had already reached a high level in Russia and to which has since been added original work by Delone, Chebotarev, Helfond Schnirelman, Vinkov, Vinogradov and others. Russian mathematicians now occupy a leading place so far as the theory of numbers is concerned. The investigations of Chebyshev, Markov and Lyapunov have played a leading part in the development of the theory of probability, and their work has been maintained by Russian science, thanks to the work of Bernstein, Kolmogorov and Hinchin.

The abstract side of Russian mathematics soon liberated itself from foreign dependence and reached a level such that the eyes of mathematicians abroad began to turn towards Moscow, thanks to work on abstract mathematics by Luzin, Suslin Uryson, P. Alexandrov and others. This side of mathematics began to develop on concrete and at the same time general problems in the newest branch of geometry, namely, topology, and on problems in algebra and analysis allied to it. New and important results in this field have been obtained by Pontyagin, P. Alexandrov, Kolmogorov and others.

The work of Russian mathematicians on analysis has many-sided characteristics. The qualitative theory of differential equations, which has numerous applications in astronomy, electricity, and so on, was dealt with before the Revolution in profound and original work by Lyapunov. This field has been taken up by N. Krylov, Bogolyubov and others. In the general theory of differential equations great progress was made before the Revolution, as is recorded in works of Steklov and Bernstein, and since by Alppo-Danilevsky as well as by Petrovsky and Sobolev.

The application of methods of mathematical analysis to problems in mechanics, the theory of elasticity and hydromechanics has given very important results, as can be seen in the work of A. Krylov, Muskhalishvili and Lavrientyev, the last-named having propounded an important general theory concerned with the functions of a complex variable. More recently, a young Soviet scientific worker, A. Alexandrov, by the application of new methods, has produced important new geometrical results.

We cannot in this short article describe in anything like detail the many and varied achievements of Russian mathematics during the twenty-five years which have elapsed since the October Revolution. We propose to deal here only with some examples of pure mathematical investigation in algebra and geometry.

Algebra, which may be defined as the science of the abstract study of operations in addition and subtraction, can be carried out not only with numbers but also with vectors, oscillations in alternating current circuits, etc. Every combination the elements of which can be subjected to the operations of addition and subtraction is called a cumulative group. From this it can be seen that the study of cumulative groups is of extreme importance. The problem requiring solution was the explanation of the properties of continuous cumulative groups and a method of investigating them. This problem was first solved by the Russian scientific worker, L. S. Pontyagin, with the aid of a method which he originated and which has since been successfully applied to other branches of mathematics.

Geometry is the science of figures, and although many geometrical problems are subject to visual proof, their solution is nevertheless often very difficult. In 1916, the well-known mathematician, Weil, propounded a fundamental problem of convex surfaces which he himself could not solve in its entirety. In 1940, A. Alexandrov showed that Weil's problem could be solved as a special case, and developed a new general method in the theory of surface areas. The fundamental part of the results obtained by Alexandrov is his discovery of a theorem of polygons which, though simple to formulate, is far from simple to prove. This theorem makes it possible to build up a convex polygon from pieces of paper cut to certain shapes. It may seem strange that what is at first sight an interesting problem for a child should be the basis of profound geometrical theories. Even such a problem, however, offers the greatest difficulty in solution.

Apart from purely theoretical investigations, Russian mathematics pays considerable attention to the solution of problems of an immediately practical character. Among problems of this nature we may point to research in the theory of the aeroplane, particularly by Christianovich and Keldysh, to work on rational laws of gunfire, on the movement of a shell, on the calculation of dams by Senkov's system, and other similar problems. At the present moment, when the U.S.S.R. is carrying on a great struggle against Fascism, these problems are of primary importance and occupy many of our leading mathematicians. It would be interesting to deal with these problems in greater detail, were it not for the fact that their significance in the present War compels us to keep them secret.

From this very short sketch, it can be seen that Soviet mathematics has attained a very high level. There are in the Soviet Union a number of outstanding mathematicians working in all realms of mathematics, and there is our own original school of mathematics, which, although it omits various branches, makes it certain that further development of the science of mathematics lies ahead in the U.S.S.R.

APPLICATIONS OF PHYSICS TO THE HEATING AND VENTILATION OF BUILDINGS*

By A. F. DUFTON
Building Research Station, Watford

> "The subjects of warming and ventilating, although in themselves simple, still deal with things and motions which are impalpable and invisible, and must be studied in their principles to be understood at all. Where the bodily eye can see nothing the mind's eye must note important processes. The peculiarity of the subject is proved by the fact of so many distinguished architects and engineers failing signally in undertakings to warm and ventilate."—Neil Arnott.

SO early as 1784, James Watt used steam for warming the room in which he commonly wrote, and his radiator, a box three and a half feet long, two and a half feet wide and one inch thick, was made of tin plates. The warming effect of this radiator, however, was less than he anticipated. The fact that Watt's expectations were not fulfilled serves as a reminder that engineering is, in a great measure applied physics and that practical advances follow as and when progress is made in experimental physics We now know that the radiator of 1784 did not emit sufficient heat because its surface was metallic, but it was not until 1801 that John Leslie discovered the nature and ascertained the properties of what is termed radiant heat.

Leslie found that the application of a coat of pigment to a metallic surface, instead of retarding the discharge of heat, nearly doubled it. He remarked that this fact, equally curious and important, was most contrary to the prevalent notions, and seemed not to have been hitherto observed. He showed that a tin canister, filled with hot water, cooled considerably faster after it was covered with flannel, and required the further addition of one or two folds to make it cool at the same rate as before. "These remarkable facts," he declared, "bid defiance to the loose sort of philosophy, which, without requiring any exertion of mind, pretends to explain everything. They teach us the necessity of a sober scepticism and demonstrate the great utility of extending a critical inquiry into the various popular branches of physics."

---

* From a lecture delivered before the Institute of Physics on November 17.

Radiant heat is not a simple entity and we must distinguish, for example, between the radiation which we receive from the sun and the radiation from bodies at temperatures of, say, 0°–100° C. The wave-lengths of the radiation we receive from the sun are all less than $3{\cdot}0\,\mu$, and the wave-lengths of the radiation from a body at low temperatures are all greater than this.

It is interesting to recall that the infra-red rays were first discovered by Sir John Herschel in the course of a research into the properties of various kinds of coloured glass, undertaken with the view of the selection of suitable glass for use in viewing the sun through a telescope. He wished to discover which of the sun's rays furnished the greatest quantity of light without inconveniencing the eye with unnecessary heat. He observed that the heat became more and more considerable as a thermometer was moved towards the red rays in the solar spectrum, and found not only that the heat continued beyond the limit of the visible spectrum but also that it was there more intense than at any point within the spectrum.

The diathermanous power of a substance differs greatly with the heat from different sources. Glass is a notable example. It transmits freely the heat of the sun, but intercepts all the radiation from a source at a temperature below 100° C. This property of glass enables us to trap the sun's heat in greenhouses and in dwellings. Glass transmits only six per cent of the heat emitted by a source at 400° C.

It must be emphasized that, in general, the absorbing and reflecting powers of a surface for low-temperature radiant heat are different from the corresponding absorbing and reflecting powers for solar radiation. Ignorance of this has led to much confusion, since the property which bodies possess of absorbing, emitting and reflecting radiant heat meets with many applications. In that old text-book, Ganot's "Treatise on Physics", we are told that the outsides of stoves and hot-water apparatus ought to be black, to give free exit to the heat. This is quite erroneous; the colour of the paint makes no difference to the emission of heat from hot-water apparatus so long as the paint does not contain metallic flakes. Metallic paints, such as aluminium and bronze, vary somewhat, the average emissivity being about 50 per cent. An appreciably lower emissivity than this is said to be obtainable, presumably by taking care not to cover the metallic flakes with too much of the binding material. In the case of an ordinary cast-iron radiator, painting with aluminium paint is found to reduce the emission by about 10 per cent; the heat communicated directly to the air, which in the case of an ordinary radiator is greater than that emitted as radiation, is unaffected by the nature of the paint used.

When we remember for how long buildings in Great Britain have been heated by means of open fires, it is difficult to understand why so much reliance has been placed upon radiant heating and why the air-warming fireplace has never become popular. Such a fireplace heats a room by means of convection currents, the heat imparted to the air causing it to circulate throughout the room. Of the experimental physicists who have advocated such fireplaces the best known is probably Benjamin Franklin, who in 1745 described his newly invented "Pennsylvanian fireplace", by the use of which he reckoned to save no less than five sixths of the fuel required to heat a room. The Pennsylvanian fireplace was preceded by the fireplaces of M. Gauger, who in 1713 published a treatise on the subject which was translated into English by a physicist, Dr. Desaguliers, and published in 1716 under the title "The Mechanism of Fire made in Chimneys".

Some four years ago I contrived an air-warming fireplace in my own home and now obtain probably three times as much useful heat from the fuel burned as before. Even in midwinter, with snow lying, there is no difficulty in heating the room so that at a distance of 20 ft. from the fire the air temperature is 70° F. This fireplace is an adaptation of the "Cheminée de Nancy" of two centuries ago.

When heating is intermittent, as is frequently the case, it is important to reduce the heating-up period to a minimum, both for economy and convenience. The problem is a physical one, and the basis for the necessary analysis was laid by Baron Fourier in his "Traité de Chaleur". It is now clear that for the most efficient use of intermittent heating the walls of a room should be lined with wood or other insulation of small thermal capacity; I believe that my experiments were the first to illustrate this. I measured the rate of warming of a room in my own home before and after I lined it with oak panelling. Without taking the furniture into account, only half the boundary surface of the room was changed by the panelling—the ceiling, window, floor and door were not affected—yet the change in the room was remarkable. The room is now warmer after half an hour than it used to be after an hour and a quarter's heating. From the practical point of view the important fact is not that one hour's heating now suffices instead of two, but that a fire may reasonably be lit half an hour before the room is wanted.

To turn now to the applications of physics to ventilation. In order to ventilate a room, an aeromotive force is necessary and the movement of air must be properly directed and controlled, especially if draughts are to be avoided. To illustrate how this may be done it is of interest to see how a physicist ventilated his house and, as an example, I cite Sir John Robison's house in Randolph Crescent, Edinburgh, and quote from the description given in 1839 by John Milne, an Edinburgh architect.

"The system of ventilation employed in this house appears to be as perfect as can be desired; as while the mass of air in the rooms and passages is constantly undergoing removal by the escape of vitiated air above, and the admission of large supplies of fresh air from below, no currents are perceived in the apartments, which, even when crowded with company and amply lighted, preserve a remarkable freshness of atmosphere. . . . This is effected by means of cylindrical flues of earthenware, nine inches in diameter, built into the gables, in close proximity to the smoke flues of each room. The lower ends of these ventilating flues open into spaces between the ceilings of the respective rooms and the floors of those above them; and there is one or more of these exit air-flues in each room according to its size and use. The heated and vitiated vapours pass upwards through the ceilings by a continuous opening of about one inch and a half wide (behind one of the fillets of the cornice) all round the rooms, and having thus passed into the space between the ceiling and the floor immediately above, they ascend by the flues in the wall, and are discharged by them into the vacant space between the ceilings of the attics and the roof; from whence they find their way through the slates to the open air. The passage for the air through the cornice is not visible from the floor of any of the rooms. . . . The continued supply of fresh air to the lower part of the house, to replace that which goes off by the ventilators and by the chimneys, is brought in from the garden behind the house by a passage, the sectional area of which is eight superficial feet. The cold air admitted by this passage (or by a similar one from the front of the house) is made to pass over a stove. . . . The usual temperature of the air issuing from the stove is as low as 64°. The whole of this air is discharged into the well of the staircase, which forms a reservoir from which the rooms draw the quantity required to maintain the upward currents in the chimneys and in the ventilating flues. The air in the staircase finds its way into the apartments by masked passages, of four or five inches wide and four feet long, over the doors, and by openings left under each door of about one inch wide. The sectional areas of these passages are more than equal to the areas of the chimney and ventilating flues . . . the quantity of escape is regulated by hand by means of throttle-valves at the mouth of each escape-flue. . . ."

It is interesting to note that, when asked in 1841 whether experience had suggested any alterations or improvements, Robison replied that, if the house were to be built again, the only difference he should make would be to form the air-passages still wider. To return to the present century, I can testify that one of the pleasantest living-room atmospheres which I have experienced was in a room provided with a ventilated cornice.

The temperature of a room with air and walls at different degrees is not easily specified. From the point of view of comfort, it is the rate at which heat is lost from the body which seems to be important, and the equivalent temperature of an environment is defined as that temperature of a uniform enclosure in which, in still air, a sizable black body would lose heat at the same rate as in the environment, the surface temperature of the body being one third of the way between the temperature of the enclosure and 100° F. The scale of equivalent temperature, introduced by me in 1929, is essentially a refinement of the sensation scale; it is measured by a eupatheoscope. When the instrument is placed in a room with air and walls at, say, 62° F. and the air is still, it indicates 62° F. If there is a draught of some 200 ft. per minute in the room, the instrument 'feels colder' and indicates 56°. The eupatheoscope is primarily an instrument for research.

Heating engineers are dependent to a great extent upon rule-of-thumb and in this age of progress are finding some difficulty in adapting standard practices and calculations to meet modern requirements. In the Heating Laboratory of the Building Research Station at Watford, we have a room with walls, ceiling and floor exposed to controlled conditions, and it is possible to study not only different methods of heating, the problems of intermittent heating and the influence of ventilation upon heating, but also those phases of building construction of interest to heating engineers. The temperature of the air in the enclosure is controlled by means of an extensive system of panel-warming and panel-cooling pipes in the walls, floor and ceiling. This enclosure is defined when the temperatures of the various surfaces are specified. The walls of the enclosure are heated or cooled by means of calcium-brine pumped through the embedded pipes, and the mean surface temperature of each wall is individually controlled to 0·1° F. by a copper resistance thermometer in conjunction with a sensitive relay system. Each wall-surface is tested once in every six minutes and the controls then automatically raise or lower the temperature of the brine by means of specially designed modulating valves.

The laboratory is designed for comparative work, and the most common form of heating in use at the present time—by cast-iron radiators—has been chosen as a standard of reference. This not only provides a convenient yardstick but also ensures that a substantial body of data is obtained about this important type of heating. The Institution of Heating and Ventilating Engineers has taken a great interest in the work at the Building Research Station, and there would have been no Heating Laboratory without the help of the Institution.

To many people the applications of physics which are of particular interest are those concerned with the development of automatic mechanisms. In this connexion I would like to invite attention to the contributions made by Dr. Neil Arnott, who was not only an eminent physician but also a competent experimental physicist. It is a hundred years ago now since Arnott produced his 'thermometer stove', the temperature of which was directly controlled by a thermometer. He applied also the unequal expansion of two small bars, one of iron, the other of brass, to the control of the air supply for a stove; but his most elegant device was the 'balanced valve regulator' which he used to regulate stoves and boilers; one of which served a small steam engine which worked a ventilating pump for months, night and day, having the attention only of a gardener, who put a supply of coal into the hopper morning and evening. With this regulator the air-flow is determined by the pressure exerted upon a plate. The weight placed on the steelyard is a measure of the quantity of air admitted to the fire and, with uniform combustion, a measure of the quantity of fuel consumed and of the heat produced.

I have mentioned a few of the physicists who have made practical contributions to the arts of heating and ventilation. Of all that has been achieved, however, in the field of heating research, there is nothing which quite compares with the work of Count Rumford. He was a great experimenter and devised methods of measurement and made determinations not only of the specific heats of various substances and the thermal conductivities of insulating materials but also of the calorific values of fuels. He strove to find out how to heat and light buildings economically and well. This was a subject which he had much at heart, and when he founded the Rumford Medal of the Royal Society, he wrote to the president:

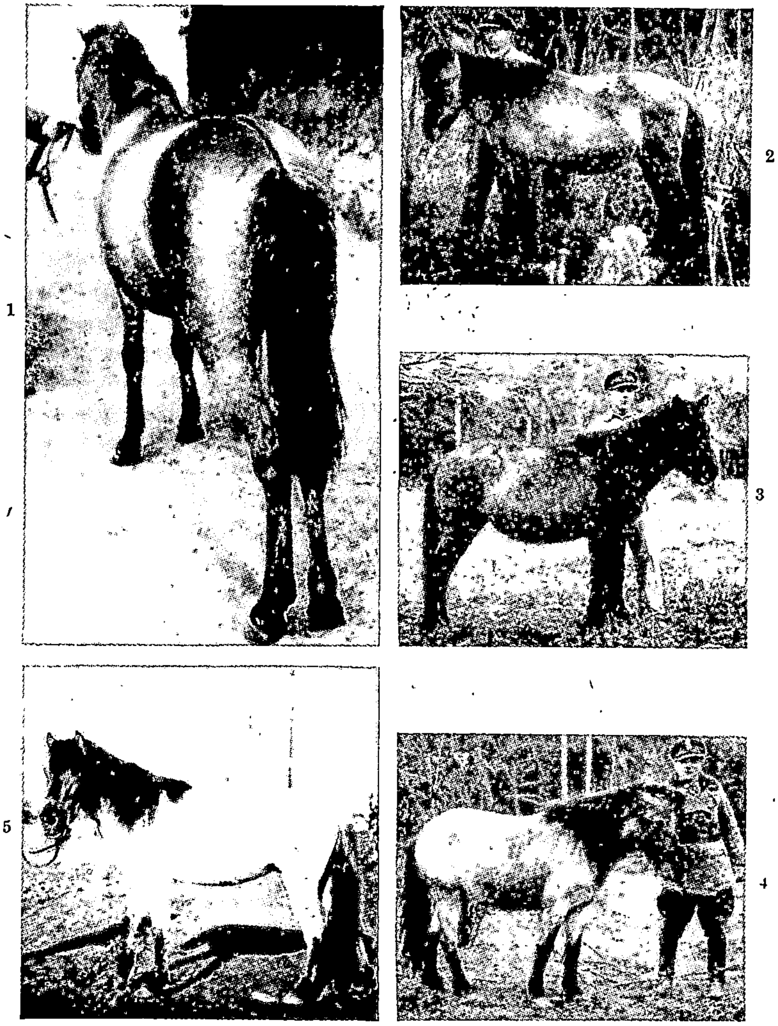
"The objects which I had more particularly in view to encourage, are such practical improvements in the generation and management of heat and light as tend directly and powerfully to increase the enjoyments and comforts of life, especially in the lower and more numerous classes of society."

THE WILD HORSE OF POLAND

By T. JANIKOWSKI

Formerly of Warsaw

WHILE studying the literature of the fossil remains of Scottish prehistoric animals I came across many interesting data recorded by the eminent Edinburgh zoologist, Prof. J. Cossar Ewart, on the subject of the hypothetical wild 'forest horse' of Scotland. According to Ewart it must have been "a stout horse with a heavy mane and tail, short strong legs, thick fetlock, joints and hoofs", a "type to which belong many of the stout, short-necked, round-quartered, deer-stalking ponies of the Scottish Highlands", with a face that is "broader and at the same time shorter . . . the outline of the face being concave". Until recently, the existence of such an animal, either in the history of man or in prehistoric times, lacked satisfactory proof. In view of the uncertainty concerning the Scottish 'forest horse' I should like to record certain facts about an interesting type of horse which still exists in Poland. This horse, the so-called *konik* (literally 'little horse' or 'pony'), formed the subject of an extensive study by Prof. T. Vetulani, of the University of Poznań, and also later by Prof. S. Hiller, of the University of Wilno (Vilna).



(1) THE BILGORAY "KONIK", WITH THE CHARACTERISTIC BLACK STRIPE ALONG THE BACK. (2) THE STALLION "TREF" IN AUTUMN, BEFORE TURNING WHITE. (3) THE MARE "CZAJKA" IN AUTUMN. (4) THE MARE "CZAJKA" IN WINTER. (5) THE STALLION "TREF" IN WINTER.

The *konik* is a small domesticated peasant-horse common in the district of Bilgoray, about lat. 50½° N. and long. 22¾° E. It is of a mouse-grey colour with a black stripe along the back from the mane to the tail. It can live remarkably long and still retain its vigour. Indeed, Vetulani reported having seen a pony still hard at work at the age of twenty-six years. The *konik* differs from the steppe horse in several aspects, having well-rounded body lines, an abundant mane and tail, relatively short limbs, a small height, a characteristic 'dished' or concave profile of the skull, a face which is remarkably short in comparison with the cranium and with the width of the forehead. Generally speaking, its features are strongly reminiscent of those typical for Ewart's horse. On the other hand, however, the *konik* bears some resemblance to still another extinct horse, the steppe tarpan (*Equus caballus gmelini* Ant.). The structure of the cheek teeth, and especially the width of the chewing surface as well as the simplicity of the enamel patterns, point to the oriental origin of the *konik*. The tarpan resembled the mouse-gray Bilgoray pony in its colour, its short dished face and some other marks, but differed in its lighter build, higher and more slender limbs; it also had a shorter and erect mane and no forelock. Taking all this into account, Vetulani arrived at the conclusion that the *konik* must be related to two varieties, the wild steppe tarpan, extinct at the end of the last century, and a second, unknown variety which possessed the features of the 'forest horse' of Ewart. He therefore introduced a new name for the Polish *konik*, the 'forest tarpan' or *Equus gmelini* Ant. *forma silvatica*, and he pictures the origin of the *konik* in the following manner.

With the onset of steppe conditions in Europe—in the glacial period and later—the steppe tarpan spread from the steppe bordering on the Black Sea to central and north-west Europe. However, the dry steppe climate did not last for ever. Gradually it became moister, and forests replaced the great grassy regions. The tarpan, an animal adapted to the conditions prevailing in the vast prairies, had to retreat step by step from the north-west to the Black Sea regions of its ancestors, where it remained as a living wild animal until 1880. In that fatal year the last tarpan lost its life after a fierce chase by hunters (Antonius). Of the tarpans which did not return to the Black Sea shores, some must have lost their lives because of the severe weather conditions. Others, more persistent and hardier, became inured and adapted themselves to the new conditions of life in the forest, undergoing gradually modifications in their bodies and developing at last into the new forest horse. Fossil remains of the latter are found throughout all central and north-west Europe, together with the remains of other members of the forest fauna such as the red-deer, roe-deer, boar, wild cat and elk.

A close examination of these remains reveals striking differences from the original tarpan; a shorter face and shorter limbs, two peculiarities which we also find in the mouse-grey *konik* as well as in some breeds of Scottish ponies. According to Ewart, "of a hundred Shetland ponies examined . . . twenty-five had most of the points of the Forest Variety". The two peculiar qualities, the brachycephaly and the micromely, are often thought to be connected with changes of the pituitary body. The hypophysis, which was of cord-form in the steppe tarpan type, became broader in the forest Bilgoray pony; the basis of the gland became flatter and developed a depression in the anterior part. Corresponding to this the sella turcica has changed also. From a regular pit it became irregular, with a convexity in the anterior part. In its inner structure the pituitary body of the forest *konik* shows a reduced amount of the glandular substance of the anterior lobe. According to Vetulani the climatic influences induced these changes in the hypophysis first, and the changes in muscular tissue followed in consequence. A strong development of the muscles with thicker muscular fibres and a higher content of the intramuscular connective and adipose tissue must have had a decisive influence on the bones.

Historical records show that the district which was inhabited originally by the wild forest horse, from which later the domesticated Bilgoray pony developed, was the Great Forest of Bialowieza, about lat. 52¾° N. and long. 24° E. This famous forest was visited in the eighteenth century by the Frenchman Hacquet, who saw the living wild forest horse with its short and erect hair of the mane and described it in his work published in 1794. The nineteenth-century Polish author Kozmian records that the wild forest horse of Bialowieza was brought at the end of the eighteenth century into a private forest zoo-park of Count Zamoyski near Bilgoray. One winter, at the beginning of the nineteenth century, when the cold was uncommonly severe, the horses, until then living free, were captured and distributed among peasants of the neighbouring villages, where, tamed and crossbred, they gave rise to the mouse-grey peasant ponies, a considerable number of them retaining the pure blood of their wild ancestors.

In 1936 Vetulani made an attempt to breed the forest horse back to its wild state. Among the animals which were brought back to the Great Forest of Bialowieza, a Polish national park, were the stallion "Tref" and the mare "Czajka", both of which had the remarkable and unique property of turning *white* in winter in a manner characteristic for certain other animals such as the hare, grouse and ermine. Every winter they changed the mouse-grey summer coat, distinguished by the black stripe on the back, into a snow-white coat, only the face, fetlocks, mane and tail retaining the dark colour.

After three years of breeding the number of horses in the Bialowieza Park rose to eighteen, out of which eight have been born free in the forest. Some of them inherited the property of becoming white in winter. According to Vetulani, the enigmatic wild white horse described by Herodotus as grazing in the northern marshy land may well have been the Polish wild pony grazing in the Polesie bogs situated close to the Bialowieza Forest.

It may be regarded now as definitely established that: (1) the 'forest horse' postulated by Ewart existed in olden times as a wild animal in many a forest of north-west and central Europe; (2) its last true wild descendants lived in the Great Forest of Bialowieza in Poland until the latest decades of the eighteenth century; and (3) some of the living wild forest horses were brought into a forest park and were later domesticated and to a certain degree cross-bred.

HIGH-CONCENTRATION HYDROGEN CYANIDE FUMIGATION OF FUNGI AND BACTERIA

By DR. N. POLUNIN

Department of Botany, University of Oxford

THE highly toxic effects of hydrogen cyanide on animals are almost proverbial, and it is now well known that its main action causing their death is through interference with the respiratory enzymes[1,2]. Since these systems appear in general to be similar in animals and plants (including yeasts and bacteria[3]), the chief of them being found in representatives from all of the plant and animal phyla[4], it might be expected that exposure to hydrogen cyanide would also kill plants easily. So far is this from being the case that hydrogen cyanide 'fumigation' is commonly employed as a means of killing insect pests on greenhouse plants which are little if at all adversely affected by the process; it is also extensively used in plant quarantine and against scale insects of citrus trees[5]. Even as it appears that a high rate of respiration is more important than the size factor in determining the susceptibility of different animals to the higher concentrations of hydrogen cyanide[6], so it now seems likely that the usually greater resistance of plants to hydrogen cyanide is largely bound up with their generally much slower rate of metabolic activity.

Fungi and bacteria being "amongst the most actively respiring plants"[7], one might have expected them to be relatively easily affected by hydrogen cyanide were it not, perhaps, for their frequently high content and rate of turnover of sulphur[3,8]. For, in low concentrations, hydrogen cyanide, even if application is prolonged, may have little or no ill effect upon living organisms, owing to its being rapidly "converted into harmless combinations with the aid of sulphur supplied by compounds of albumen"[5]. However this may be, and in spite of the fungicidal and bactericidal properties of gaseous hydrogen cyanide being "extremely poor" in such concentrations and over such times of application as have usually been tried[5,9], the following observations show that in heavy doses hydrogen cyanide can be lethal to both colonies and spores (or other disseminules) of such moulds and bacteria as were to be found in the air of two rather dusty rooms. Considering the effect of fairly high concentrations of the gas on green plants[5,10] this was indeed to be expected but surprisingly enough does not appear to have been previously observed or at least not adequately recorded.

The observations referred to were made in connexion with the recent fumigation by a London firm of two rooms in our Druce Herbarium in North Oxford. This fumigation was principally against the drug-store beetle, *Sitodrepa panicea* (Linn.), and lasted about fifty hours. The concentration of gaseous hydrogen cyanide aimed at was in excess of thirty mgm. per litre (about 2·6 per cent 'by vol.'); some such maximum was probably reached within the first hour in the larger free spaces, but with little doubt the concentration in the atmosphere thereafter fell markedly owing to leakage and absorption[11]. The weather was favourably warm, throughout, though the temperature was slightly below normal for August, while intermittent rain kept the relative humidity high. For the observations malt agar Petri plates were prepared in considerable numbers by my colleague Dr. W. H. Wilkins, to whose assistants, Dr. G. C. M. Harris and Mr. Cripps, my sincere thanks are also due; Dr. Wilkins also kindly supplied the cultures mentioned below. Although most of my experiments were replicated either six or ten times by the use of as many plates, so that a considerable area of nutritive surface was exposed and incubated for each observation, it must be noted that apart from some germination tests performed later the only medium used was malt agar, which does not preclude the possibility of exceptions to these observations being afforded by organisms which do not normally grow on this very good 'all-round' medium (for example, at 25° C.).

Three days before the commencement of the fumigation, malt agar plates were exposed for ten minutes in various parts of the rooms concerned. After incubation for sixty-eight hours at 25° C. these plates supported from six to twelve evident fungal and bacterial colonies each. A few of the plates were left in the incubator as controls, but the majority were exposed, together with a number of fresh sterile plates and others supporting vigorous cultures of *Penicillium frequentans* Westling and *Aspergillus* sp., in various parts of the two rooms throughout the *c.*50 hours of the fumigation, before the beginning of which the air in the rooms had been rendered dusty by the shifting of herbarium material and furniture. In spite of the prevailingly favourable conditions of temperature and relative humidity, it appeared at the end of the fumigation that the 'exposed' colonies had not grown at all during its course; nor was there any sign of growth on any of the previously sterile plates. All these plates that had been exposed during the fumigation were now incubated at 25° C. for five days and nights, at the end of which period the results still appeared the same, that is, the previously sterile plates bore no sign of life while all colonies remained the same size as at the beginning of the fumigation. (A striking contrast was afforded by the plates that had been left in the incubator as controls instead of being exposed during the fumigation; dense growths now practically filled all these.) Before replacing in the incubator the infected plates which had been exposed to hydrogen cyanide, fresh sterile plates were inoculated from a number of the colonies on them; also, plates which had been sterile when exposed to hydrogen cyanide were so inoculated while other such plates were inoculated from vigorously growing cultures of several different moulds and one bacterium. After incubation for three days and nights there was no sign of growth in any of these cases, though quite large colonies had by this time developed on the pertinent controls (fresh plates inoculated at the same time from growing cultures). Nor was there yet any sign of life on any of the other plates that had been exposed during the fumigation, and, in some instances, afterwards aired with the covers off (these covers probably had little effect on the retention of any residual hydrogen cyanide by the medium[12]); nor would spores from these 'exposed' colonies germinate even much later in hanging drops of distilled water.

The conclusions thus seem inescapable that the colonies had all been killed by the fumigant and that the malt agar plates had all been rendered inhibitant to growth—at least of such saprophytic and aerobic fungi and bacteria as had been represented by spores in the air of the rooms. This inhibition lasted at least eight days but began to disappear thereafter; thus ten days after the cessation of fumigation a slight growth was observed from contaminations or fresh inoculations on some of the plates that had been exposed to hydrogen cyanide, though others appeared incapable of supporting growth even from any spores present in the air of the laboratory until several more days had elapsed.

It will be noted that, unfortunately, it was not determined whether the colonies were killed by gaseous hydrogen cyanide or by that adsorbed by the agar gel (the *p*H of which was probably not affected[9]), though the appearance and texture of dense growths of mould after the fumigation suggested that the gas alone had sufficed to kill them. Again, the spores of the air may merely have been unable to germinate on the surface of the 'exposed' medium —although those belonging to the colonies appeared to have been killed outright by the gas. These and most of the other obvious doubts could easily be settled by *ad hoc* investigation. But meanwhile the possibilities of useful application of such a method for the apparent sterilization of an entire system of rooms and their bulky contents are not inconsiderable, especially if damp colloidal material remains inhibitant to the growth of destructive saprophytic organisms for 1–2 weeks as did the agar plates in my observations. As examples we may consider how frequently nowadays tobacco is so mouldy as to be practically worthless when bought, and how much valuable material has been lost in bombed museums and stores because it was soused by rain or firemen's hoses and could not be dried before going rotten; fumigation, even if not long maintained, might well delay decay until all could be effectively handled and dried. For such purposes the practicability and relative merits of other fumigants should be investigated immediately (unfortunately sulphur dioxide, which is known to be more toxic[9] to fungi and bacteria than hydrogen cyanide, could not be used in herbaria, etc., owing to its bleaching action). A probable advantage of hydrogen cyanide is that in general bacterial growth is checked by very dilute solutions of it[6,13], while residual traces are very persistent[12] although the gas is notoriously penetrating; a disadvantage may lie in the uncertainty of any action on anaerobes which lack cytochrome components[3,4] but are able to break down carbohydrates[14]. From all these points of view the possibilities and limitations of formaldehyde should be further explored.

OBITUARIES

Mr. William R. S. Ladell

Mr. William R. S. Ladell, whose sudden death in Jamaica on November 6 has just been reported, was born in 1887 and educated at the Merchant Taylors School and Finsbury Technical College. Before completing his degree, he went abroad and started work on agricultural science in the tropics, which was to occupy the greater portion of his life. After three years in South Africa with the Department of Agriculture, part of which was at the Cedara Experimental Station, he accepted in 1912 a position with a commercial company in Malaya, where he carried out many field and laboratory experiments on rubber cultivation. During the War of 1914–18 he served at first in the Far East and later in Great Britain and reached the rank of major in the Royal Army Ordnance Corps.

After the War, Ladell took up an official appointment in Siam and in 1923 was put in charge of the newly formed Bureau of Agricultural Science. The greater part of his work for the next twelve years was connected with problems of rice cultivation, in which he obtained a world-wide reputation. During this period also he developed a keen interest in general natural history, particularly entomology, and was for many years honorary secretary of the Natural History Section of the Siam Society.

In 1934, owing to the disturbed political situation in Siam, Ladell returned to England and worked for four years in the Entomology Department at Rothamsted on problems of soil insects and insecticides. His wide experience and chemical knowledge was here a great asset and he developed the method of separating insects from the soil by flotation in a heavy solution.

In 1938 an opportunity occurred for Ladell to return to the tropics, where his heart was always, and he became agronomist and soil chemist to the West Indian Sugar Company in Jamaica. There he found congenial work, and shortly before his death he had been appointed chief research officer for the Associated Sugar Companies of the Island and editor of a new Journal, *Sugar Technology*.

Ladell was elected a fellow of the Chemical Society in 1907, of the Institute of Chemistry in 1911 and of the Royal Entomological Society in 1929. He was very modest in character and a pleasant and enthusiastic colleague; he is survived by his wife and three children.

C. B. Williams.

Flight-Lieut. A. N. David

Flight-Lieut. David, who died recently on service at the age of fifty-three, had been associated with the Forest Products Research Laboratory at Princes Risborough since its earliest days in 1922, when he joined the Department of Scientific and Industrial Research after his retirement from the Indian Forest Service.

After being educated at Aldenham and Oxford, David joined the Indian Forest Service in 1911, and between 1916 and 1919 saw service as a pilot in the Royal Flying Corps. At the outbreak of war in 1939 he at once rejoined the R.A.F.V.R., receiving a mention in dispatches shortly before his death.

During his connexion with the Forest Products Research Laboratory, his work was mainly concerned with the collection of home-grown timber for the various investigations, and the related information on the field conditions of its growth. His cheerful, hard-working personality secured the ready collaboration of the woodland owners, without which it would have been very difficult to obtain suitable material. The collection of field information needed much painstaking work in all sorts of weather; indeed bad weather seemed to dog his expeditions, but never stopped him. His contribution to the work of the Laboratory was most useful, though attracting little attention to itself.

Sir Charles Hyde, Bt.

We regret to record the death at the age of sixty-six of Sir Charles Hyde, proprietor of the *Birmingham Post* and its associated papers. He was, perhaps, relatively little known outside Birmingham except in newspaper circles and on the racecourse, for he shunned publicity. In Birmingham he was known as a most generous philanthropist. Born at Worcester, the son of a surgeon, he was educated at Clifton and Exeter College, Oxford. At the age of twenty-one he entered the newspaper world at the invitation of his uncle, John Feeney, then proprietor of the *Birmingham Post and Mail*; on the death of his uncle he became, in 1913, the proprietor of the *Birmingham Post*, *Birmingham Mail* and *Birmingham Weekly Post*. To the University of Birmingham Sir Charles gave freely, contributing £10,000 to the appeal fund in 1920. He also bought and equipped a large house in Edgbaston as a hostel for men undergraduates, now known as Chancellor's Hall. In 1925 he gave a further £100,000, part of which was to be devoted to the building of the Students' Union, a fine building which has been of supreme importance in the social life of undergraduates. He also gave £10,000 for a Joseph Chamberlain Memorial Museum in the University Medical School.

Sir Charles was a munificent supporter of Birmingham hospitals, the Children's Hospital in particular. He was chairman of Queen's Hospital and from

1919 until 1926 was chairman of the War Pensions Hospital Committee.

Archæology, too, benefited by his generosity, for he financed the excavations at Viroconium, near Wroxeter, of which the results have lately been published. Farther afield his help enabled the University of Belgrade to resume excavations on the prehistoric site of Vincha. He also bore the cost of British Museum excavations at Nineveh and assisted an expedition working on the Necropolis at Vounous Bellapais in Cyprus. His name will long be remembered with gratitude. G. A. SHAKESPEAR.

WE regret to announce the following deaths:

Dr. E. J. Allen, C.B.E., F.R.S., secretary to the Marine Biological Association of the United Kingdom and director of the Plymouth Laboratory from 1895 until 1936, on December 7, aged seventy-six.

Prof. R. A. Gortner, professor of biochemistry in the University of Minnesota, on September 30, aged fifty-seven.

Prof. T. M. Putnam, professor of mathematics in the University of California, on September 22, aged sixty-seven.

NEWS and VIEWS

Reconstruction in Great Britain: The People

THE widespread interest in the problems of post-war reconstruction and planning was reflected in the House of Commons debate on December 1 and 2 on an amendment to the Address. The debate was characterized by notable speeches from Mr. Greenwood, Sir William Jowitt and Mr. Anthony Eden. Sir William Jowitt gave a comprehensive but general account of the Government's policy. Sketching the post-war position and stressing the importance of international co-operation in a deliberate effort to improve the standard of living throughout the world in order that consumers abroad may be able to buy that which we produce, he said that he believes we must become as a nation more scientifically minded, prepared, whatever industrial system we adopt, to use scientific methods and to aim at the greatest efficiency in those methods. The Ministerial Committee over which he presides is, he said, trying to work out practical schemes of reconstruction to which effect could be given in the first few years after the War, and presupposing in its plans a social and economic structure designed to secure equality of opportunity and service among all classes of the community. The Ministerial Committee is assisted by an external and an internal committee of highly placed and experienced Civil Servants. Demobilization plans are being prepared; these include the question of education and training for those whose educational careers have been interrupted by the War. With regard to getting the workers back into industry, the Government considers that each industry should be surveyed separately, because the structure of industry will not fit into a common mould. The points of contact between Government and industry require strengthening, and Sir William said that capital must be ready to seek new opportunities and labour must be prepared to be more fluid.

The Land

Fully accepting the views of the Scott and the Uthwatt Committees as to the need for correlating policy, the Government has decided, Sir William said, in view of the importance of maintaining Parliamentary responsibility, to ask Parliament to constitute a separate Ministry of Town and Country Planning. This Minister will be a member of the Ministerial Committee already supervising reconstruction policy, and there are also important functions for which a permanent commission, acting under the Minister of Town and Country Planning, will be the most appropriate body. The Government has reached no decision as to the acquisition by the State of development rights in all undeveloped land or on a levy on increases in annual site values, but it is proposing in forthcoming legislation to confer wide and simple powers on local authorities for the compulsory acquisition of land. In regard to food, Sir William said that the wise developments of the last few years should not be abandoned after the War. Close attention is being given to the formulation of a permanent post-war agricultural policy, on which the Dominions will be consulted. A really vigorous forestry policy will be adopted after the War, for which the Forestry Commission has been instructed to formulate a programme. Sir William also referred to the organization of electricity supply on the most efficient basis, to the close review of water supply, and finally to the place of education in reconstruction.

International Aspects

Sir William Jowitt's references to the importance of international co-operation and to collaboration with the International Labour Office were amplified in the speech with which Mr. Eden replied to the second day's debate. Reiterating our determination to assist in the immediate relief of post-war Europe, Mr. Eden pointed out that the manner in which, and the extent to which, we succeed or fail in co-operating with our Allies now will largely determine the course of post-war foreign policy. Whether we are able to maintain peace or not afterwards will depend on whether we can carry through the co-operation we have now established with the United States of America, with Soviet Russia and with China. The first need of Europe will be to build up an enduring system of defence against the possibility of renewed German aggression. He hoped that we are prepared to make our contribution to take our part because we understand that peace and security in Europe are part of our own peace and security.

Welcoming a recent speech of Mr. Sumner Welles indicating American readiness to accept world-wide responsibility for maintaining peace, and recognizing the value of the International Labour Organisation as possibly the main instrument for giving effect to Article 5 of the Atlantic Charter, Mr. Eden pointed out that for any international organization to have a chance to achieve its purpose it must be fully representative of the Powers that mean to keep the peace. Second, the Powers themselves must have the unity and the determination to arrive at agreed and positive decisions; and third, they must have the force behind them to give effect to their decisions. Mr. Eden believes that out of this organization of the United

Nations, based in the first instance on understanding between Great Britain, the United States and the U.S.S.R., a great opportunity has opened, and although the task will be heavy it can be achieved if we do not forget our lessons, and make co-operation in peace as true and effective as in the years of war.

Colonial Policy

Viscount Cranborne, until recently Secretary of State for the Colonies, replied on behalf of the Government in a debate in the House of Lords on December 3 on Colonial affairs. The keynote of his speech was the diversity of the Colonial territories. He remarked that ever since the fall of Malaya there has been a stream of criticism against the administration of the Colonies. That disaster was due, according to some, to the fact that the local peoples had not been sufficiently associated with the government of their country. This explanation, however, cannot apply to Siam, an independent State, or to the excellent administrative system of the Dutch East Indies or of the Philippines. British policy gave Malaya a long period of internal peace, justice and prosperity. The proposal for a Colonial charter presupposes a uniformity which is unattainable and probably undesirable in the British Empire. The Empire consists of a diversity of countries and peoples in all stages of development, and its administration is characterized by great variety and flexibility. There is no cut and dried pattern ; local systems have been adapted and adopted, and there has been gradual evolution in each territory of a form of government which seems best suited to promote the moral and material welfare of the people, with the ultimate aim of self-government.

A fundamental step in advancing to self-government is the provision of education. Surveying the position, Lord Cranborne said that, in the field of mass education, we have to meet first widespread illiteracy. Programmes for adult and community education are being prepared. Elementary education is spreading in Nigeria, the Gold Coast, Uganda, Mauritius and the West Indies, where Sir Frank Stockdale, comptroller for development and welfare, has been working for two years. Higher education is being developed at Achimota in West Africa, and at Makerere in East Africa ; in Ceylon, the university college has been raised to the status of a university ; in West Africa there is a scheme for an institute of arts, crafts and social sciences. Further, much consideration is being given to the education of women and girls. Medical schools are working in East and West Africa, in Ceylon, Malta and Fiji, and important investigations are being carried out by British organizations and by the Rockefeller Foundation. Social security rests, so far as the Colonial Empire is concerned, on economic security, and this in turn on agriculture ; steps for the production of food for local use have been speeded up, and mixed farming has been promoted. Labour conditions have been improved, and Lord Cranborne referred to the Exchequer grant of £5,000,000 a year under the Colonial Development and Welfare Act for approved schemes advanced by Colonial Governments.

A Survey of World Resources

In a report on "The Problem of Raw Materials" prepared by Prof. I. Högbom, of Stockholm, and issued by the League of Nations in 1937, there is a striking graph showing the world production of the principal minerals and metals during the period 1860–1937. Sir Harold Hartley uses this graph as the text of an article, published in *The Times* of November 27, on the need for a survey of world resources. The graph is plotted on a logarithmic scale and demonstrates that production of aluminium, tin, copper, phosphates, petroleum, pig iron, coal and lignite had a steady rate of growth until 1914. Then the general rate decreases sharply, to be followed by violent oscillations during the past twenty-five years. The end of the period of steady increase marked the end of territorial expansion and exploitation, accompanied by failure to realize that world conditions had changed, and that a planned economy was required. Such a plan is implicit in the orderly economic collaboration of the United Nations envisaged in the Atlantic Charter. The goal is "greater stability of world conditions and increased well-being based on the better use of world resources, full employment and the development of backward areas". The foundation of any scheme directed towards this end is a world survey of production and consumption.

Sir Harold points out that the data for the pre-war years are mainly available, though they need bringing together, and the Allied Bureau under Sir Frederick Leith-Ross is dealing with the immediate post-war period. The preparation of estimates for a more stable form of society to succeed this period is a more difficult matter, in view of the fluctuations of the past twenty years. Such long-range estimates must be 'moving targets' subject to such factors as population trends, knowledge of basic needs and the development of backward countries. Estimates of consumption must precede estimates of production, to be followed by surveys of distribution. The data for these estimates, some of them already available through the activities of individual countries and industries, or committees set up by the United Nations, are at present unco-ordinated, with unknown gaps, and, in Sir Harold Hartley's opinion, a United Nations Economic Bureau should be appointed to deal with the matter.

Temperature of the Atmosphere

A further colloquium in the series arranged by the Manchester University Branch of the Association of Scientific Workers was addressed by Dr. T. G. Cowling on December 2, the title being "The Temperature of the Atmosphere". Dr. Cowling began by describing how the temperature of the lower part of the atmosphere is determined by radiation, convection, and advection (horizontal currents of air and water). The distribution of temperature over the earth's surface varies with the season, and in consequence sudden large fluctuations in temperature due to the passage of air masses are in the British Isles more probable during winter than summer. Turning to the variation of temperature with altitude, Dr. Cowling suggested a possible explanation for the fact that the temperature ceases to decrease at a height known as the tropopause. According to this theory, solar energy is absorbed by ozone in the stratosphere, and in the absence of any gas with strong emission bands in the infra-red, the temperature is increased. Water vapour has broad intense bands in the infra-red, and when it is present tends to keep the temperature low. In considering variations of the temperature in the stratosphere with season and latitude, account must be taken of any variations of the concentrations of gases such as ozone and water vapour, as well as of the intensities of the radiations coming from the sun and earth. During the discussion which followed, Dr. L. Jánossy pointed out that the tropopause falls rapidly at the same latitude that shows a marked increase in cosmic ray intensity. Cosmic rays might conceivably produce some ozone, and so account for the higher temperatures over the poles.

Recent Earthquakes

THE United States Coast and Geodetic Survey, in co-operation with Science Service and the Jesuit Seismological Association, has determined the epicentres of two recent earthquakes. The first was on September 26, 1942, and took place at approximately 4h. 00·3m. U.T. It had an epicentre near lat. 12·8° N., long. 87·5° W., which is in the region south of the Golfo de Fonseca in Nicaragua in Central America. The second occurred on October 21, 1942, at about 16h. 22m. 15s. U.T. and had an epicentre near lat. 33·1° N., long. 116·0° W., which is to the west-north-west of Imperial in Southern California.

That the earth blocks, the movement of which caused the very severe earthquake of December 27, 1939 in Anatolia, have not yet attained their position of equilibrium is shown by the earthquakes and tremors which still occur in the district. The latest strong shock of this series occurred about 10 p.m. local time on December 3. At Ciorum, sixty miles from Ankara, the tremors lasted 25 seconds according to human perception. Four people are reported to have lost their lives and nine were injured in Central Anatolia.

Sir William Power, F.R.S. (1842-1916)

SIR WILLIAM HENRY POWER, an eminent Victorian epidemiologist, was born at Bosworth on December 15, 1842, the son of a medical practitioner. He was educated at University College, London, and qualified in 1864. After serving as resident medical officer at the Victoria Hospital for Diseases of the Chest, where he gained much valuable information in connexion with tuberculosis, he was appointed in 1871 temporary medical inspector in the Local Government Board, where he made a special study of the small-pox epidemics in London of 1871–72 and 1881 and upheld the theory of the aerial convection of disease, particularly in relation to the Western Hospital, then known as the Fulham Small-Pox Hospital. The publication of his "Statistics of Small-pox Incidence in the Registration Districts of London relating to the Operation of Small-pox Hospitals in the Metropolis" led to the permanent removal of all small-pox cases occurring in London to extra-metropolitan hospitals, a practice which still holds good. His other publications included reports on epidemics of diphtheria in Warwickshire and Essex, an outbreak of scarlet fever in certain districts of London believed to be due to milk, and lead poisoning by public water supplies. In 1871 he was appointed assistant medical officer in the Local Government Board, and in 1889 succeeded Sir Richard Thorne Thorne as senior medical officer, when he did valuable work in connexion with the Food and Drugs Acts and the Royal Commission on Tuberculosis. In 1895 he was elected a fellow of the Royal Society. He was also awarded the Jenner Medal of the Epidemiological Society of London, the Bissett-Hawkins Medal of the Royal College of Physicians and the Stewart Prize of the British Medical Association. He died on July 28, 1916.

Marius Sophia Lie (1842–1899)

ON December 17 occurs the centenary of the birth of the distinguished Norwegian mathematician Marius Sophia Lie, who was born at Nordfjordeif, near Bergen. Educated at the University of Christiania (Oslo), he took his doctorate in 1868 and, after gaining a travelling scholarship, visited France and Germany, making the acquaintance of Klein, Darboux and Jordan. In 1872 a special chair of mathematics was created for him at Christiania, but fourteen years later he returned to Germany to succeed Klein at Leipzig. He returned to the Norwegian capital in 1898, and died there on February 18, 1899. Lie was recognized as one of the most original and independent workers in pure mathematics; he was elected a foreign member of the Royal Society, and the Cambridge Philosophical Society and the London Mathematical Society added his name to their lists of honorary members. Referring to his death, Larmor said, at the meeting of the British Association in 1900, "We have lost one of the greatest constructive mathematicians of this century, who has in various directions fundamentally expanded the methods and conceptions of analysis by reverting to the fountain of direct geometrical intuition".

Admiralty Appointments

THE appointment is announced of Commander C. F. Goodeve, F.R.S., R.N.V.R., reader in physical chemistry at University College, University of London, to the post of assistant controller (research and development) in the Admiralty. Commander Goodeve will be responsible for the co-ordination of research and development in the departments of the Controller of the Navy, and for ensuring that scientific opinion is adequately represented in those Departments and that due weight is given to it.

Sir Stanley V. Goodall, director of naval construction, has been given the additional appointment of assistant controller for warship production. He will remain the principal technical adviser to the Board of Admiralty on the design of warships and other vessels for the Royal Navy. In his capacity as assistant controller for warship production he will be responsible under the Controller of the Navy for the production of warships and their completion with all appropriate supplies, and for the necessary co-ordination to achieve the fastest possible results with the greatest economy of effort.

Announcements

SIR JOHN RUSSELL retires on September 30, 1943, under the age limit, from the directorship of the Rothamsted Experimental Station. Sir John Russell succeeded Sir Daniel Hall in 1912 and during his thirty-one years as director the Station, the oldest agricultural institute in the world, has shown a remarkable expansion of its research activities and of its authority in agriculture.

MR. HARRY R. RICARDO, who is well known for his outstanding work in connexion with internal combustion engines, has been elected an honorary member of the American Society of Mechanical Engineers, New York.

IN recognition of his distinguished services as rector of the Imperial College of Science and Technology during 1929–42, Sir Henry Tizard, president of Magdalen College, Oxford, has been elected a fellow of the Imperial College.

Production of Penicillin

PENICILLIN, the metabolic product of *Penicillium notatum*, discovered by Fleming in 1929, has been shown to be a chemotherapeutic agent of great importance. The exceedingly high bacteriostatic potency of this substance, together with its low toxicity to tissue cells, are such that penicillin has been described as "the most powerful antibacterial agent with predominantly bacteriostatic action so far known"[1], and its value in human therapy has already been demonstrated[2].

It is, therefore, unfortunate that the production of crude penicillin is a somewhat lengthy process in which the yield of this valuable but unstable product is small[1,2]. Further, the process involves the culturing of the mould in large volumes of fluid medium in culture vessels in which the depth of medium is small. The incubation space therefore required is so great that the facilities of even the larger laboratories are inadequate for the production of penicillin in quantity sufficient for therapeutic use, or for the further work required in the elucidation of its chemical structure. By the modified method of production outlined below, the bacteriostatic metabolic product of *P. notatum* is produced in 5–6 days in yield comparable to that obtained in 10–11 days by the method as previously described[1,2]. This means that for a given incubation space the *output* of the crude active substance may be considerably increased (for example, doubled) and, in addition, the modified method has other advantages.

Attempts were made to increase the yield of penicillin by adding to the medium (as used by Florey *et al.*[2]) substances which might serve as growth factors. In this connexion it was thought that the culture fluid itself might contain such substances. Therefore, small quantities (0·1–10 c.c.) of fluid from an 11-day culture of a previous batch were added to culture vessels containing 200 c.c. of medium, after which the bottles were seeded with *P. notatum* and then incubated at 24° C. along with cultures to which no culture fluid was added. These experiments were strikingly successful and the course of the metabolism was profoundly altered as judged by the following criteria: growth and sporulation of the mould, pigmentation of the culture fluid, *p*H changes and appearance of coloured droplets on the surface of the mycelium were all considerably accelerated as compared with untreated cultures (controls), and the rate of production of the antibacterial substance after 4–5 days' incubation, as judged by the ring assay test described by Florey *et al.*[2], was increased considerably. However, these results were not maintained during further incubation, the assay tests then indicating a considerable diminution in the amount of antibacterial substance present in the culture fluid. Observations of the changes in the *p*H of the culture fluid suggested that the antibacterial substance was being destroyed by the excessive amount of acids produced under the changed experimental conditions.

Accordingly, similar experiments were carried out in a medium adequately buffered by the addition of a strong solution of mixed phosphate buffers, the proportion of the mono- and dihydrogen phosphates being determined after consideration of the *p*H ranges most favourable for the stability and production of penicillin. The results of these experiments were entirely satisfactory, and the amount of antibacterial substance produced in 5–6 days (so far as could be judged by ring assay tests on the *diluted* culture fluid, and by the serial dilution method as used by Fleming[3]) was at least equal to that produced in the control experiments in 10–11 days, that is, in cultures seeded from the same suspension of the mould and incubated along with the test cultures. Assay tests on the culture fluid after several days' more incubation (in addition to the 5 days) showed no diminution in the amount of active substance present, and work is in progress in order to ascertain if the yield of the active substance *per given volume of culture fluid* may be increased, that is, as compared with the yields obtained in 5–6 days by the modified method or in 10–11 days by the older method.

Pigment production during the shorter incubation period of the modified method was less than in the 10–11 day period of the unmodified method, and this is an advantage of importance, since the isolation and purification of the active substance will therefore be facilitated.

In preliminary experiments, buffering of the medium as in the successful experiments outlined above, but without the addition of the culture fluid, appeared to alter the metabolism of the mould as in the experiments in which both culture fluid *and* buffer were added. Further work is in progress in order to ascertain whether the addition of culture fluid is necessary.

At present only small quantities of the crude antibacterial substance have been prepared by the modified method. The substance, however, was found to be extractable at *p*H 2 by amyl acetate and from the amyl acetate solution the active substance was re-extracted at *p*H 6·4 with aqueous barium hydroxide. There is therefore no reason to doubt that the bacteriostatic metabolic product of *P. notatum* produced was penicillin, although rigid proof cannot be brought forward until the active substance has been isolated in a more highly purified form.

Experimental Production of a Pouch in the Male of *Trichosurus vulpecula*

THE female of *Trichosurus vulpecula*, the common Australian phalanger or possum, has a well-developed pouch, while the male possesses in the corresponding region a large pendulous scrotum. On injecting large doses of œstrogen into males of varying ages there appeared at the sides of the scrotum skin folds which strongly suggested the formation of a rudimentary pouch, particularly in immature animals[1].

To obtain more definite information as regards the true nature of these folds the small scrotal sac of three pouch young of three to four months of age was amputated with or without the testes.

The best result was obtained from a pouch young of three months of age where the testes occupied a position external to the body wall but had not actually entered the scrotal sac. The scrotum, measuring about 0·2 cm. in length, was amputated while the testes were left behind. A fortnight after this operation 40 I.U. of gonadotropin obtained from human pregnancy urine was injected intramuscularly, and a month after the operation 0·1 mgm. of œstradiol dipropionate was administered. Second and third injection of 0·2 mgm. of œstradiol dipropionate was given respectively one week and three weeks later.

Due to the amputation of the scrotum the testes remained separated. However, already after the first injection of œstradiol dipropionate a V-shaped ridge of raised tissue containing the separated testes as well as the remaining scrotal elements became very prominent. After the second injection of œstradiol dipropionate definite infolding of the abdominal skin along this ridge became visible and a recess was formed beneath it. A few days later a typical pouch had formed, though its swollen and puckered lips were still diverging cephalad at an angle of about 45°. After the third injection of œstradiol dipropionate the animal was capable of closing the lips almost completely, thus presenting a fully developed pouch similar in size and shape to that found in females of about equal age treated with œstrogens. The small and elongated testes became situated in the lips of the pouch and were not discernible on superficial examination.

In the case of the other two pouch young of about four months of age the scrotum with the now descended testes was amputated. Prior and immediately after the operation these animals were also given chorionic gonadotropin. A few weeks after the removal of scrotum and testes œstradiol dipropionate was administered in amounts of 0·1–0·2 mgm. In both these animals a typical pouch was also formed but the results were less perfect than in the first experiment because in one instance no apposition of the lips could be obtained. In the other animal there was an infolding of the skin along the almost closed lips except where they joined at the caudal end of the experimentally produced pouch. These imperfections were probably due to the fact that in the more extensive operation of removing a larger scrotum containing the testes, more of the elements required for the formation of the pouch were removed. After establishing a pouch all three animals lived for about another month and then died, apparently from the toxic effect of the administered œstrogen.

In contrast to the finding of Burns[3], that both scrotum and pouch of the polyprotodont marsupial *Didelphys virginiana* do not react to hormone treatment, the experiments now described in conjunction with others[1,2] on the diprotodont, *Trichosurus vulpecula*, indicate a far-reaching hormonal control over these organs. They appear to be definitely homologous, the pouch being an invagination and the scrotum an extrusion of the same area of abdominal skin which is characterized by the presence of only a little muscle.

Onions and Vernalization

IN connexion with work on the induction of flowering, an attempt was made to vernalize onion. It is known that autumn-sown onions occasionally become thick-necked in the following summer. In February of this year, onion seed of the varieties James Long Keeping and Ailsa Craig was germinated at 23° C. Those seeds in which the radicles were just emerging (one day after soaking) were subjected to a temperature of 2° C. for three weeks and seven-eight weeks and were planted out in seed trays; they were kept in a greenhouse until mid-March and the end of April respectively and all transplanted in the open air on May 7, together with untreated controls germinated on February 25, and also on April 1 in the case of Ailsa Craig.

In September last flowers were seen on some of the Ailsa Craig plants which had been vernalized for three weeks, and by October 21, 10 of the 37 plants bore flowers. In no other treatment were flower-buds produced, though in all, thick-necked bulbs preponderated except in James Long Keeping unvernalized. No flowers opened, though the bracts of three inflorescences have parted, and all inflorescences are in healthy condition at the present time (November 24). JEAN MARGARET FRY.

A Red Colouring Matter from the Green Leaves of Spinach Beet

THE production of a red colouring matter from an extract of the green leaves of spinach beet, reported by Marsden[1], is capable of explanation on the basis of a well-known redoxase-chromogen relationship.

The aqueous extract of the green leaves may be assumed to contain a colourless or lightly-coloured chromogen. The aqueous extract of raw potato has been tested by the benzidene, α-naphthol and guaiacum tests and found to contain oxidase, peroxidase and catalase. The expressed cell-sap of spinach-beet leaves contained only peroxidase and catalase.

When these two extracts are mixed the chromogen reacts with the oxidase with the production of the brownish-red pigment. The probability that the action is of an oxidizing character is increased by the fact that shaking speeds the production of colour. Soaking leaf-tissue in aqueous hydrogen peroxide for an hour imparts a brown colour to the sap of epidermal cells. The presence of a chromogen would seem to be confirmed.

The brownish-red colour suggests an oxidized anthocyanin as reported by Jones[2]. In its reactions with caustic soda and hydrochloric acid, and ferric chloride solution, it agrees with the pigment from beetroot. But with sodium carbonate solution the spinach-beet pigment gives a bright yellow solution while that from beetroot gives a violet solution. Neither pigment is appreciably extracted from acidified aqueous solution by amyl alcohol or a 1 : 5 mixture of cyclohexanol and toluene. Both pigments slowly fade on heating.

Optical Reflections from Coal

THE classification of the petrological constituents of coals developed in Great Britain by Dr. Marie C. Stopes and published in a revised version in 1935[1] has been widely adopted as a basis for further research in many directions. Much more attention appears, however, to have been given to petrological and chemical than to physical properties. Many workers give density determinations and C. Mahadevan has made an X-ray diffraction study of coals[2]. In general, measurements for the coal properties selected have cut across the Stopes classification when they have been determined for vitrain, clarain, durain and fusain. Typical results taken from Hoffmann's paper[3] are given in Table 1 showing the maximum variations in samples taken from different seams in the same coalfield, and the overlap between the constituents.

TABLE 1. SAMPLES FROM TWELVE MINES IN SAAR COALFIELD SHOWING MAXIMUM VARIATIONS.

Constituent	Ash	Volatile matter	Specific gravity
Vitrain	0·4– 2·2	27–36	1·2–1·9
Fusain	1·0– 8·0	9–18	1·4–1·7
Clarain	0·7–11·0	32–47	1·2–1·4
Durain	0·3–45·0	29–62	1·2–1·7

From the wide range of variations, it would appear that if an attempt were made to select a specimen of one of the constituents on the basis of the quantitative data alone, a mistake might easily be made. Since so much work has been done by so many workers on the subject, some property or properties of coal must have been used first to select, without doubt, from a lump of coal a specimen of, say, vitrain. Dr. Stopes's reference to "such ingredients, in hand specimens, as are visibly different from each other", suggests the relevance of optical properties. (Elastic properties are also involved in the detailed description, given in the large table "A Classification of Coal Ingredients", accompanying Dr. Stopes's paper.)

An attempt has therefore been made to study quantitatively the optical properties of coals. Specimens were prepared by cutting, grinding and polishing plane surfaces on the samples of the petrological constituents (with the exception of fusain). The specimens were mounted, in turn, on the table of a spectrometer in which the telescope had been replaced by a photo-electric cell unit for measuring light intensities. With the collimator fixed, the coal surface was mounted in a vertical plane reflecting the incident parallel beam of light. At various fixed angles of incidence, the intensity of the light reflected in the region of the specular angle was measured. Typical results are shown in Fig. 1 for the region around a specular angle of 60°. The spreading of the reflected beam is greatest for fusain, least for vitrain, with durain lying between the two. Data are not given for clarain, which in the new Stopes classification is regarded as vitrain mixed with some of the microscopic constituents of durain and fusain. Fig. 2 is a typical curve for the variation of maximum intensity of reflection with angle of incidence, showing, as grazing incidence is approached, the rapid increase in intensity of reflection characteristic of dielectrics.

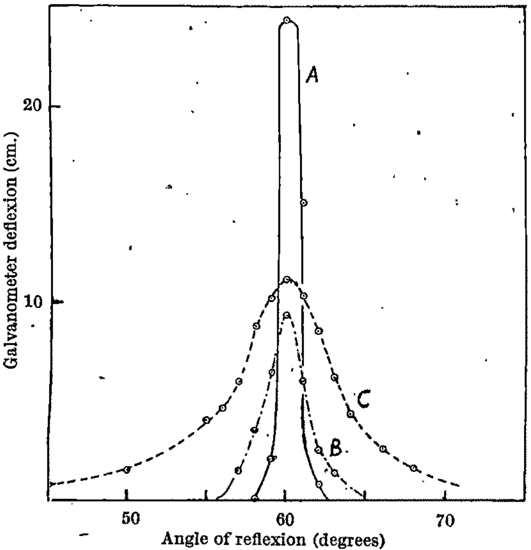

Fig. 1. VARIATION OF REFLECTED INTENSITY AROUND THE SPECULAR ANGLE WHEN THE ANGLE OF INCIDENCE IS 6°. *A*, VITRAIN ; *B*, DURAIN ; *C*, FUSAIN.

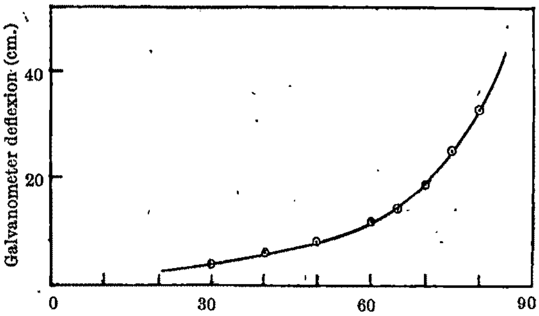

Fig. 2. VARIATION OF MAXIMUM INTENSITY OF REFLEXION WITH ANGLE OF INCIDENCE.

The method was then applied to typical specimens of some of the petrological constituents from different types of coals and the results are shown in Table 2.

TABLE 2. SPECULAR REFLECTION FOR POLISHED COAL SURFACES AT 60° ANGLE OF INCIDENCE AND REFLECTION.

Sample and description		Galvanometer deflection (proportional to intensity)	Percentage reflection (approx.)
	(Incident intensity approximately 150 cm.)		
DURAIN	Warwickshire	3·5 cm.	2·0
	Northumberland	5·2 cm.	3·5
CANNEL	Derby	7·6 cm.	5·0
VITRAIN	Freeburning coal, Yorks.	8·6 cm.	5·7
	Coking coal, Durham	9·7 cm.	6·5
	Freeburning coal, North'd	10·7 cm.	7·1
	Bright coal, Derby	10·9 cm.	7·3
	Bright coal, Warwick	10·9 cm.	7·3
	Anthracite, S. Wales 1....	11·1 cm.	7·4
	Anthracite, S. Wales 2....	14·7 cm.	9·8
	Anthracite, Durham	23·6 cm.	15·7

It would appear that the petrological constituents fall into groups ; for example, durain 2–4 or vitrain 5·7–15·7, giving a quantitative classification corresponding with that of Stopes, allowing individual variation, without the overlapping of the groups common to quantitative determinations of other properties. Although the numerical values are altered by the method of treatment of the surfaces, the distinctions remain if the different surfaces are given comparable treatment.

Thanks are due to Dr. D. H. Bangham, principal scientific officer of the British Coal Utilization Research Association, for his kindness in providing free access to the Association's collection of samples.

SCIENTIFIC FILMS IN TEACHING PHYSICS

A DISCUSSION on "Scientific Films and their Use in the Teaching of Physics" was held at a meeting of the Physical Society, on November 20. It was opened by Mr. W. Ashhurst, who pointed out that more lecturers and teachers would use films if they knew more about the technique of their use and could obtain sufficient suitable ones.

Undoubtedly there will be a great increase in the number of projectors in use after the War. The War has seen a wide increase of use of the film as a training and propaganda medium. The fighting Services and Home Guard are now using projectors. The Ministry of Information has equipped and trained a corps of projectionists; potentially, this service, now devoted to propaganda, could be a magnificent adjunct to educational media in peacetime. We may well be at the beginning of a revolution in teaching and demonstration techniques. It is urgent that science teachers should have clear aims and a clear attitude to this medium. The film should be treated as an essential part of public education and public service, as are laboratories, gymnasia and clinics. The few projectors in use in England can be contrasted with the large numbers in use in other countries.

Mr. Ashhurst then referred to an article by Mr. Oliver Bell, director of the British Film Institute, in the *Documentary News Letter*, in which it is suggested that the Government should be prepared to spend £1,500,000 in ten years on visual education.

On the production side, Great Britain has created some good scientific films, but so also have other countries, and "Mouvements Vibratoires" is an example of French lucidity and elegance in the making of a science teaching film.

The cinema has much power in the class room. It can enliven the teaching of pure science and can also point dramatically and vividly to its applications. It appeals in a familiar way, and, with suitable guidance by the teacher, important information can be impressed upon the memory. The film brings the outside world into the class-room. In science teaching, the application of fundamental principles in industry can be presented in a manner from which, very often, more can be learned than by actually taking a tour around a workshop or industrial plant.

The film has obvious advantages over the blackboard for illustrating a moving mechanism. Animated diagrams can be exceedingly clear. Quickly moving objects can be photographed using slow-motion photography, which is useful in engineering, and peeded-up photography is largely responsible for the uccess of plant-life films. Both these techniques have obvious applications for the practical exposition of physics problems.

The old controversy of the relative merits of sound and silent films may be resolved by stating that each has its own particular uses. Undoubtedly, the majority of science teachers prefer to supply the commentary. Each topic should be treated in the manner more suited to it. Obviously, a film illusrating a demonstration of a 'sound' experiment should be a 'sound' film, and, similarly, a film about olour should be in colour. It thus follows that most expositional films should be silent, whereas application or background films, sound. Generally speaking, a film which is to be run straight through should use sound, for then the commentary would be carefully worded and synchronized; in contrast, a teacher's extempore commentary would be very inferior.

A film should not be used in place of a demonstration.

The diagrammatical film can be drawn perfectly and 'animated'. A special type is the cycle or loop film. Loop films are used in the representation of cyclic actions. Their unique value is in memorizing cycles and presenting physical and mathematical rhythmic phenomena in a vivid way.

There are at least four ways of using films in the class room. (1) As an illustration comparable in its use with a lantern slide. An example of this type, which should necessarily be short, is the cycle film. It is a brief demonstration introduced as incidental to the theoretical lesson. (2) As a basis for a film lesson. A special lesson is given based on the particular film. It is necessary for the teacher to know the film well and build around it. Different teachers have different methods, but the value of the film is lost if it is not discussed fully afterwards and the important points pressed home. Many teachers commence the lesson by a showing, then, by questions, analyse its content and deal with the theory involved, finally concluding the lesson by a second showing. Experience shows that the attention should be directed before, or during the showing, to important things. There is always the tendency for the attention to wander on to something of lesser importance. (3) For revision purposes. There is a great possibility for such films. A good ten-minute film can revise effectively the work of several lessons. (4) To show the application of fundamental principles and possibly their social implications. Here, background films are employed, and with their aid the class is taken from the class room to the factory or industrial plant. The scope of such films is unlimited and their value obvious. It is through the social and industrial documentary that science joins hands both with the rest of the curriculum and the outside world.

The opening remarks were followed by a showing of various films. These were selected to illustrate the different types, namely, the illustrative film, the film for the film lesson and the background film.

In the discussion which followed, opinions were stated by members, some experienced and others inexperienced, in film use. Many physicists are prejudiced against the use of films, as physics deals with real things, not pictures. Moving diagrams may be annoying, but perhaps, as the pupil becomes familiar with such representations, he may not be so affected. The film may offer a solution in special cases where laboratory and demonstration facilities are not good; for example, in workshop schools far removed from a technical school. On no account should irrelevant matter be included: the teaching film should be full of substance and devoid of theatrical packing.

There are clearly great possibilities for films depicting the lives and work of the great men of science. The few such films already in existence, for example that on the life of Pasteur, are obviously not suitable for use as a whole in schools. Excerpts might perhaps be made, but it would be very much better to prepare films specially for school use, giving particular attention to the limitations imposed by class-room conditions as regards both time and physical difficulties.

ASSOCIATION OF UNIVERSITY PROFESSORS AND LECTURERS OF ALLIED COUNTRIES IN GREAT BRITAIN

As the established bodies for intellectual collaboration were obliged to cease their work owing to the War, universities being in many cases closed down in the occupied countries by the invader, scholars, professors and lecturers from all over the world gradually made their way to England, where they now have their headquarters and are living and working in all parts of Great Britain.

This assemblage seemed to present a unique opportunity for men of mutual interests and intellect to come together and form an Association. A few professors of different nationalities, headed by Prof. Stefan Glaser of Poland, decided to start an Association, the aims of which are the reconstruction of universities in the occupied countries after the War, the development of an academic fraternity between allied university teachers and research workers now in Great Britain, the consideration of all academic problems both during the War and in the post-war period, collaboration with any other bodies which may have similar interests, the examination of problems referred to it by any of the Allied Governments or by any other appropriate official bodies.

The first general meeting was held on May 11, 1942. From the very first there was a great deal of interest and enthusiasm and an organization was formed under the title of "Association of University Professors and Lecturers of Allied Countries in Great Britain". There are at present 225 members and twelve countries are represented, besides India and the British Dominions.

As the whole subject of post-war reconstruction and education is a long and very complex one, it was furthermore decided to get in touch and collaborate with other associations of similar interests. Contacts were made with the British Association for the Advancement of Science, the British Association of University Teachers, and the American University Union. Several neutral countries, which may have representatives as guests, have been approached, and all the vice-chancellors of universities in Great Britain have been informed of the programme of work.

Since the Association has to deal with different domains and subjects, it was decided to form separate sections in order that members should be able to collaborate on subjects of mutual interest. There are at present twelve such sections:

(1) Contact and collaboration with British scholars; organization of lectures of Allied professors in Great Britain (*Provisional chairman*, Prof. P. Vaucher).

(2) Collaboration with other international bodies; international research centre in Great Britain; international review of science and learning (*Provisional chairman*, Prof. J. Timmermans).

(3) Reconstruction of science and learning in the occupied countries (*Provisional chairman*, Prof. S. Glaser).

(4) Re-education of youth after the War and alleviation of moral damage; future collaboration (elaboration of common programmes of teaching, improvement of existing programmes, exchange of students and teachers, acknowledgment of Allied diplomas in Great Britain and so on); elaboration of main principles of the future social order; international university (*Provisional chairman*, Mr. Randall Lane).

(5) Law (*Provisional chairman*, Prof. A. L. Goodhart).

(6) Science (*Provisional chairman*, Prof. A. Photiades).

(7) Economy (*Provisional chairman*, Prof. J. A. Veraart).

(8) Modern humanities (*Provisional chairman*, Prof. L. Genissieux).

(9) History (*Provisional chairman*, Dr. Yuen-li Liang).

(10) Technical science and engineering.

(11) Medicine, as distinct from general science (*Provisional chairman*, Prof. J. Skladal).

(12). Philosophy.

The executive committee consists of sixteen members, namely:

Belgium: Prof. Jean Timmermans; China: Dr. Yuen-li Liang; Czechoslovakia: Prof. Vladimir Klecanda; France: Prof. René Cassin, Prof. Paul Vaucher; Great Britain: Sir Alfred Zimmern, Prof. B. Ifor Evans, Prof. W. Entwistle, Prof. R. Douglas Laurie; Greece: Prof. Alexander Photiades; Netherlands: Prof. J. A. Veraart; Norway: Prof. A. Sommerfelt; Poland: Prof Stefan Glaser, Prof. B. Helczynski; United States of America: Prof. A. L. Goodhart; Yugoslavia H.E. Prof. Milan Grol.

The officers of the Association and of the executive committee are: Prof. Stefan Glaser (president) Prof. Jean Timmermans (vice-president); Prof. B Ifor Evans (secretary-general); Prof. Paul Vaucher (treasurer).

The second general meeting as well as a meeting of all sections will take place on December 16 at the Rembrandt Hotel, Thurloe Place, S.W.7, at 4 p.m Information concerning membership or details regarding the work and aims of the Association can be obtained from the Secretary for the Association, 4 Queen's Gate, London, S.W.7.

A NEW SOCIAL CONTRACT

By D. CARADOG JONES

"Something to Look Forward To"* is the title of an ingenious pamphlet by Lady Rhys Williams in which a new form of social contract is outlined, capable in her view of providing security and a fuller home life for the ordinary men and women of Great Britain "within the framework of our democratic constitution, and without destroying or even greatly altering the present organization of industry, finance, and the machinery of Government" She does not agree with those who maintain tha economic security for the worker is only possible subject to the nationalization of the chief sources of production. If it can be proved that, under private enterprise and the profit motive, the system which has prevailed and made Great Britain relatively rich in the past, it is possible to preserve liberty and to banish want, then it would be unwise, argues Lady Williams, to scrap this old system and substitute a new one which at best is bound to be a gamble. She offers such a proof and supports it with statistics. While it is possible to check her arithmetic—one error may be noted in the total under A(4) on p. 40—the fundamental figures on which her estimates of cost are based are given in the form of averages and it is not clear how these have been determined.

---

* Something to Look Forward To: a Suggestion for a New Social Contract. By Lady J. Rhys Williams. Pp. 54. (Cardiff: *Western Mail and Echo*, Ltd., 1942.)

The author believes that, although there would be no intrinsic difficulty in distributing to all men on an equal basis the goods which already exist, the incentive to production would quickly disappear if that were done. Nor would this difficulty be overcome by an extension of national insurance. Already, with our pre-war rates of benefit, many an unskilled labourer with several children could do better on the dole than by a hard week's work for wages. The solution proposed is in effect the free offer of a dole to everybody (though to call it bare maintenance sounds better) irrespective of their income or state of employment. This, it is claimed, would at least have the merit of not placing those who are out of work at an advantage over those who are in work.

Perhaps the term "free offer" is scarcely fair. Those who accept would be expected in return to follow their normal occupation, to register at an employment exchange, and to accept suitable work in their own line. If unemployed beyond, say, twelve months, training for a new trade would be provided or assistance in removal to another part of the country where work might be available. This is the essence of the contract.

The nature of the maintenance scheme is best illustrated by a practical example. Consider the case of a man earning £4 a week, with a wife and two dependent children. This family would get allowances for rent, fuel and light, and food in the form of non-transferable coupons valid only between certain dates, the cash value of the coupons depending on the size and composition of the family. They would be exchangeable into money, either at a bank or at the local office which issued them, by the landlords and retailers to whom they would be paid by the householder. In the particular case chosen the allowance for rent would be 7*s.* a week in respect of the householder and 3*s.* 6*d.* in respect of each dependant, or 17*s.* 6*d.* in all. The corresponding allowance for fuel and light would be 1*s.* 6*d.* a week for the man and 1*s.* 3*d.* for each dependant, or 5*s.* 3*d.* in all; and for food 8*s.* for the man and 7*s.* 3*d.* for each dependant, or 29*s.* 9*d.* in all. In addition the man would get a cash allowance of 3*s.* 6*d.* a week and each dependant would get 2*s.* 6*d.*, making 11*s.* in all. Thus the cash value of the total benefits payable to this household would amount to 63*s.* 6*d.* We must offset against this a flat-rate tax of 7*s.* 6*d.* in the pound, which it is proposed to levy on the first £250 of all incomes, or 30s. in this case. Hence the net weekly gain to the family would be 33*s.* 6*d.*

Certain supplementary benefits are proposed covering health, education, and funeral costs. All these would be a clear addition to wages, military and nurses' pensions, and other forms of retirement pay. But old age and widows' pensions, also benefit under the Health Insurance Acts, would be superseded by the new scheme. Unemployment benefit, on a reduced scale, would still be paid to those out of work through no fault of their own; but unemployment assistance and public assistance, apart from exceptional cases, would cease.

The flat-rate tax mentioned above is estimated to provide roughly four fifths of the money required (£2,070 million) to finance the scheme, the balance to come from savings on existing social service expenditure and economies due to bulk-purchase of foodstuffs, to which are added the benefit of present food subsidies and a grant of some £100 million from the Exchequer.

The idea of providing free State maintenance for the poorest section of the population has attracted many thinkers, if only as a means of tidying our conglomerate social services by a clean sweep. It will be interesting to compare Sir William Beveridge's solution of this problem, not made public at the time of writing, with that of Lady Williams. Before her interesting plan receives serious consideration, no doubt the question will quite reasonably be asked whether it is really necessary. Admitting, as she apparently does, that the machinery of production, if fully utilized and directed to the satisfaction of human needs, is capable of providing "undreamed of prosperity", should not such full utilization provide employment for all, and should not wages, salaries, and profits rise in step with production—without any drastic change in the economic system—granted that enough (but not too much) credit is always made available to circulate the goods? Nevertheless, the proposals contained in the pamphlet provide refreshing food for thought for all who are interested in the major question of the future: the disposal of surplus production.

SHIPBUILDING AND RESEARCH

THE seventeenth report of the Select Committee on National Expenditure, dealing with merchant shipbuilding and repairs, points out that the rate of output of merchant ships has been greatly increased since the beginning of the War. The programme of merchant shipbuilding which was set for 1941 was substantially attained, and in the first six months of 1942 the programme was slightly exceeded. The arrears of repair work have been cleared off, partly as a result of a decline in the amount of repair work, but partly also because of improvements in organization. The output per worker has greatly increased and has probably never been higher. In one region it increased by one half between February 1941 and June 1942, and the evidence is that in spite of American advantages in labour supply and the absence of black-out restrictions, the output per man in tons of steel in the American yards is about half that in the British yards.

In the view of the Admiralty the greatest difficulty is in obtaining sufficient labour, and the Select Committee concurs in pointing out that for a larger shipbuilding programme further measures will be required to provide the necessary labour, by the recruitment and training of new workers, better utilization of the labour force and improving the output of each worker. Riveters present a special difficulty, and the establishment of training schools for riveters in the main shipbuilding areas is recommended under the management either of the Ministry of Labour or of private shipbuilders in their own yards. Inquiry by the Ministry of Labour into the experience gained of the employment of women in other heavy industries, as well as in shipbuilding, so far as it is available, is also recommended, to decide what trades can be carried on by women and und what conditions, and what standards of hea should be required. A larger proportion of women in the age-group 20–30 should be made available for shipbuilding, and once again the importance of welfare work is stressed and the appointment of women welfare supervisors urged.

Personnel management and questions of morale and co-operation recur in this report, as well as of management, and the Committee emphasizes the wisdom of taking all possible steps to put before the workers the full gravity of the shipping position.

It is, however, the section on technique, design and research that is of the greatest interest to scientific workers. Here a careful examination of pre-fabrication of hull portions from the point of view of economy of labour is recommended. Under present conditions, the use of welding beyond a certain point does not appear to effect any saving of time as compared with riveting by skilled squads. Expert opinion inclines to the view that in British yards a combination of the two methods will give the best output. There appears still to be some room for standardization of sections and fittings and the elimination of non-essentials, and the Committee suggests that the British Classification Societies should review their rules to ascertain how far production could be assisted without lowering standards of safety.

It is disappointing to find in this section of the report the opinion that the resources of the William Froude Laboratory have not been fully exploited for war purposes by shipbuilders or by the Admiralty. The Committee therefore recommends that shipbuilders should be instructed to consult the National Physical Laboratory at the appropriate stages in the design of all proposed new types of hull, and that the Admiralty should see that full technical liaison is maintained with the Laboratory. Similarly, commenting on the delays and interruptions in the dissemination of the results of research into the problems of merchant shipbuilding and marine engineering, and the actual decrease in such research by the Institute of Welding, the Iron and Steel Institute, or under the auspices of the three universities possessing chairs of naval architecture, since the War, the report recommends that the Admiralty should establish an organization with the specific responsibility for directing and co-ordinating all development and research in respect of merchant shipbuilding. Coupled with this there is recommended, first, the appointment, in close association with this organization, of a technical intelligence staff, and, secondly, that where several firms are building similar vessels, one of them should act as leader for each part of the complete vessel and machinery, and be responsible for development and improvement in production technique for that part.

Apart from these recommendations to rectify a disturbing lapse of research activities on the part of institutions which might properly have been expected to intensify them, there are other recommendations affecting organization, such as a survey of all yards engaged exclusively on naval work to ascertain whether a small admixture of merchant shipbuilding could assist the maximum output without impeding naval work, a review of the allocation of merchant programmes with the object of reducing the number of types of merchant ships built in the same yard, and a survey of all yards not now in use for shipbuilding, and the selection for re-opening of those which could most rapidly be brought into use. On the other hand, shipbuilding has not been delayed from lack of materials, and the main conclusion of the report appears to be that attention to the human side of personnel problems and to the organization of facilities and supplies of labour and materials in key with the demands of the country as a whole are the chief essentials to ensure the execution of a programme adequate to meet the country's needs.

TUBERCULOSIS IN WAR-TIME

TUBERCULOSIS in war-time has recently been discussed by Sir Arthur MacNalty in a Chadwick Public Lecture (see p. 676 of this issue). It is also the subject of an excellent report reviewing critically the available evidence and making recommendations, which has been prepared by a committee of the Medical Research Council (London : H.M. Stationery Office, 1942. 9*d.* net).

The Committee finds that there has been a significant increase in the incidence and mortality of tuberculosis affecting all age groups since the War began. Modern war creates social and industrial upheavals responsible for many factors which tend either to increase the risk of contact with tuberculous persons or to a lowering of resistance to the tubercle bacillus.

The Committee makes many recommendations for preventing further deterioration in the trend of tuberculosis mortality :

(i) To reduce the spread of bovine infection from milk, the widest possible extension of pasteurization should be undertaken.

(ii) To detect pulmonary lesions at an early stage, mass radiographic surveys should be made (*vide infra*).

(iii) Improvements in the care and after-care of infected persons are necessary, with special reference to increasing the number of available beds in sanatoria and to financial aid to the patients and their dependants.

(iv) In order to raise resistance to the tubercle bacillus, especially in susceptible groups of the population, close attention should be paid to the working conditions of young employees.

(v) Additional measures are suggested ; namely, the examination of contacts, investigation of tuberculosis in mental hospitals, propaganda to the medical profession and the public, and a re-organization of the tuberculosis services.

Mass Radiography

The Committee pays especial attention to the value of mass radiographic surveys of selected groups of the community to discover the disease at an earlier stage than in most cases when the diagnosis is first made. The technique of miniature radiography, especially by virtue of its speed and economy, has made mass surveying a feasible measure. It should be stated that a subject showing positive findings in the miniature radiograph is only regarded as a suspect until full clinical, bacteriological and radiological (full-size film) evidence proves or disproves the presence of significant disease.

Miniature radiography implies the photography of the fluorescent screen image produced by X-rays and is practised in two forms : (*a*) 5 in. × 4 in. miniature (as used widely in the United States) ; (*b*) 35 mm. cine film miniature recording. Many units using the cine film will shortly be available in Great Britain : a technical sub-committee (the report of which appears as an appendix) has laid down the requirements for this apparatus.

Mass radiography may be used:

(i) *Pre-employment*: examination of groups about to enter employment (e.g., the Services, industry).

(ii) *During employment*: examination of groups of persons, for example, in munition factories, without selection as to age or sex.

(iii) *Periodically*: examination of groups at regular intervals: this is regarded as the ideal method for the early diagnosis, and thus for the control, of pulmonary tuberculosis. In the difficult conditions of war-time, periodic mass radiography would probably have to be confined to specially selected groups, for example, munition workers, medical students and nurses, and merchant seamen.

In the main report, the Committee states that "mass miniature radiography requires a considerable degree of organization and planning ahead", but it is left to the Sub-Committee to emphasize that the method "should not be lightly undertaken. A very high standard of quality of miniature radiography is necessary for correct interpretation and the latter requires the highest radiological skill". It is of the greatest importance that every effort should be made to secure and preserve the highest technical standard: it is on this that the success of the method depends. The proposed vast surveys should be watched by a carefully chosen central advisory (or controlling) board of experts acting for the Ministry of Health.

TRAVELLING WAVES IN HIGH-VOLTAGE ALTERNATOR WINDINGS

A PAPER by E. Friedländer (*J. Inst. Elec. Eng.*, 89, Pt. 2, No. 11; October 1942) discusses the theory of this subject, pointing out that the security of the windings of an alternator generating at 22 kv. or above and connected directly to a network depends mainly on the ability of the insulation to withstand surge voltages. The distribution of surge voltages in the various types of stator winding hitherto adopted in commercial practice is examined, together with the relation of this distribution to that of the effective insulation available. As alternators nearly always operate with the neutral point of the windings unearthed, the voltage stresses on the insulation near the neutral in these circumstances are determined, and the danger of the use of graded insulation is discussed. In no case does there appear to be an inherent tendency for all transient voltages to be distributed over the length of the stator winding in the same proportion as the generated voltage of the machine.

The problem of the design of an alternator to generate directly at 22 kv. or 33 kv., or at higher voltages, appears to be best solved by avoiding graded insulation and applying the conventional methods of construction hitherto used for 6·6 kv. or 11 kv., the insulation being increased in thickness to carry the increased voltage. Such conventional windings have great inherent security against transient surge voltages, which affect chiefly the interturn insulation, and their major insulation can be easily and cheaply protected against more sustained over-voltages by means of surge arresters, preferably applied both to the terminals and to the neutral if this is unearthed.

These conclusions have arisen from theoretical considerations based on a number of approximations which, however, it has not been possible to check by experiment. Any experimental work, however, may be subject to considerable errors due to the depth of penetration of the flux into the iron of the core varying with the current of the conductors. The actual wave shapes found experimentally with low currents thus might not agree with the theoretical results, which are based on conditions that probably are better approached with heavy surge currents. The results obtained lend no support to the view that the distribution of the capacitances in the concentric-winding conductor would give even distribution of surge stresses over its different sections.

DISPLACEMENT METHOD OF WEIGHING LIVING ORGANISMS

A. G. LOWNDES has described* not only the method indicated by the title of his paper but also methods for determining the water content of living (especially aquatic) organisms and in some cases the density of their protoplasm. The accurate determination of the weight is (with marine animals) achieved by weighing a density bottle full of sea water and estimating the halide in the contents of the bottle gravimetrically, followed by a weighing of the bottle containing sea water and a living marine organism and an estimation of the halide content of the water in the bottle. All these data may be obtained with great accuracy and from them the author calculates the weight, volume and density of the organism.

The ratio of density of organism to density of medium (multiplied by 1,000 by the author and called the "sinking factor" or S.F.) is a measure of the effort that must be exerted by the organism to keep afloat. For the conger, the S.F. is 1,000, and so there is no tendency to sink, whereas the lobster with a higher S.F. will sink unless work is done to keep afloat, although the necessary expenditure of energy is reduced if the female lobster is carrying a load of eggs or embryos, because its S.F. is then lowered although its weight is, of course, increased.

The water content of aquatic organisms is determined by a modification of Dean and Stark's method, and here a novel technique is employed that obviates the introduction of errors due to the presence of extraneous water that wiping fails to remove. The author determines the water content of the animal and a known amount of sea water together, and from a knowledge of the composition of the latter, the amount of water in the organism is readily obtained by difference. In sponges that have been dried during a water determination, the silica is estimated and, making allowance for the presence of silica, the density of the living protoplasm is computed with a considerable degree of accuracy; minor modifications of the methods are necessary when freshwater organisms are being used. The interest of the methods lies in the high degree of accuracy attained, which makes possible investigation of the precise physiological and physical relations existing between aquatic organisms and their environment, and so paves the way for the advancement of knowledge in this field.

FORTHCOMING EVENTS

(Meetings marked with an asterisk are open to the public)

Saturday, December 12

BRITISH MYCOLOGICAL SOCIETY (at the Linnean Society, Burlington House, Piccadilly, London, W.1), at 2 p.m.—Miss E. M. Blackwell: "On Germinating the Oospores of *Photophthora cactorum*" (Presidential Address).

INSTITUTE OF INDUSTRIAL ADMINISTRATION (at Caxton Hall, Westminster, London, S.W.1), at 2.45 p.m.—Dr. J. A. Bowie: "Management Today and Tomorrow".

FREE GERMAN INSTITUTE OF SCIENCE AND LEARNING (at 16 Buckland Crescent, Hampstead, London, N.W.3), at 5 p.m.—Prof. M. Polanyi: "The Scientific Community".*

Monday, December 14

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 8 p.m.—Major J. T. Wilson: "The Mackenzie Lakes to Hudson Bay and the Routes of Early Explorers traced on Air Photographs".

Tuesday, December 15

ROYAL SOCIETY OF ARTS (DOMINIONS AND COLONIES SECTION) (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Dr. B. P. Uvarov: "The Locust Plague".

INSTITUTION OF CIVIL ENGINEERS (STRUCTURAL AND BUILDING ENGINEERING DIVISION) (at Great George Street, Westminster, London, S.W.1), at 2 p.m.—Dr. F. M. Lea: "Modern Developments in Cements in relation to Concrete Practice".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 3 p.m.—Prof. J. C. Drummond: "The History of our More Important Foods", (iv) "Fruits and Vegetables".*

Wednesday, December 16

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, South Kensington, London, S.W.7), at 6.30 p.m.—Discussion on "Soaring Flight" (to be opened by Comdr. P. A. Wills).

Thursday, December 17

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. R. P. Bell: "Recent Developments in the Theory of Reaction Kinetics in Solution" (Tilden Lecture).

Friday, December 18

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Prof. J. W. Munro: "The Place of Research in the Control of Injurious Insects".

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Dr. Adolf Meyer: "The First Gas Turbine Locomotive"; Mr. A. J. R. Lysholm: "A New Rotary Compressor".

Sunday, December 20

WORKERS' EDUCATIONAL ASSOCIATION (GLASGOW BRANCH), ASSOCIATION OF SCIENTIFIC WORKERS (SCOTTISH AREA), WORKERS' EDUCATIONAL TRADE UNION COMMITTEE (SCOTTISH AREA), and the EDUCATIONAL INSTITUTE OF SCOTLAND (GLASGOW ASSOCIATION) (in the Glasgow and West Scotland Commercial College, Pitt Street, Glasgow, C.2).—Joint Conference on "Science and the Struggle for Freedom". At 10.30 a.m.—Prof. H. Levy, Prof. V. Gordon Childe and Dr. C. Ockrent: "Science in the Struggle against Fascism"; at 2.30 p.m.—Dr. Martin Ruheman, Dr. F. Haldane and Mr. C. R. Wason: "Science in the Soviet Union".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT MASTER WITH GOOD QUALIFICATIONS IN SCIENCE, at the Southport Technical College—The Secretary to the Education Committee, Education Offices, 1 Eastbank Street, Southport (December 16).

TEACHER (MAN OR WOMAN) OF MATHEMATICS in the Technical Day School—The Clerk to the Governors, South-West Essex Technical College and School of Art, Forest Road, Walthamstow, London, E.17 (December 16).

VETERINARY INVESTIGATION OFFICER under the Advisory Scheme of the Ministry of Agriculture—The Registrar, The University, Leeds (December 21).

HEAD OF THE ENGINEERING DEPARTMENT, at the College, Swindon—The Director of Education, Education Committee, Swindon (December 23).

SPEECH THERAPIST—The Education Officer, County Hall, Wakefield (December 24).

HEADMASTER of Felsted School—The Clerk to the Governors, Mr. Norman Orfeur, Solicitor, Braintree, Essex (December 31).

DIRECTOR of the National Froebel Foundation—The Secretary, National Froebel Foundation, 2 Manchester Square, London, W.1 (February 27).

SECOND ASSISTANT PORT ENGINEER (MECHANICAL) for the Basrah Port Directorate, Iraq—The Secretary, Overseas Manpower Committee (Ref. 541), Ministry of Labour and National Service, Hanway House, Red Lion Square, London, W.C.1.

ASSISTANT MECHANICAL ENGINEER for the Tanganyika Government Railway—The Secretary, Overseas Manpower Committee (Ref. 411A), Ministry of Labour and National Service, Hanway House, Red Lion Square, London, W.C.1.

ASSISTANT ELECTRICAL ENGINEER for the Nigerian Government Public Works Department—The Secretary, Overseas Manpower Committee (Ref. 538), Ministry of Labour and National Service, Hanway House, Red Lion Square, London, W.C.1.

ASSISTANT MASTER WITH GOOD QUALIFICATIONS IN ELECTRICAL ENGINEERING, at the Maidstone Technical Institute—The District Secretary, Mr. A. W. Peacock, 13 Tonbridge Road, Maidstone, Kent.

SENIOR OFFICIAL to be responsible to the Secretary for the work involved by the scientific activities of the Institution—The Secretary, Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1 (endorsed 'Science').

TEACHER OF ENGINEERING SUBJECTS—The Principal, Wolverhampton and Staffordshire Technical College, Wulfruna Street, Wolverhampton.

ISAAC NEWTON, 1642–1727

CHRISTMAS DAY is the three hundredth anniversary of the birth of Newton, an event which, were it not for the conflict and chaos of these times, would have been celebrated on a world-wide scale, and marked by an international gathering of representative men of science in London and probably also at Grantham. In the present circumstances, we have to be content with more modest proceedings. Thus the Royal Society made its anniversary meeting on November 30 a Newton celebration, the Physical Society arranged a special lecture given in London and repeated at Cambridge, and a gathering at Grantham was addressed by Sir Henry Dale, president of the Royal Society.

It is on a similarly limited scale that the event must be marked in NATURE. Newton's life and work are surveyed by Prof. S. Brodetsky, of the University of Leeds. We also have the privilege of printing the addresses delivered by Prof. E. N. da C. Andrade, Lord Rayleigh and Sir James Jeans at the Royal Society's commemorative meeting. In the words of Sir Henry Dale, in opening that meeting, Prof. Andrade was asked to survey "the change which Newton's work produced, in the conceptions of the material universe which were current in his own times". Lord Rayleigh was asked "to deal, by demonstration where possible, with the experimental work of Newton and the great discoveries which he made by that method". Finally, Sir James Jeans was asked to give "some reassessment of the validity and permanence of Newton's system, in relation to the immense advances of knowledge in our own times".

In these four contributions, we believe we have a conspectus, brief as it must necessarily be, of the life and work of Newton. For more detailed accounts of the several aspects of Newton's work we must refer readers to the Supplement published with NATURE of March 26, 1927, on the two hundredth anniversary of his death. That issue included also a representative collection of portraits, and photographs of the well-known statue in Trinity College Chapel, Cambridge, and the Manor House at Woolsthorpe.

On p. 731 of this issue we reproduce an interesting document belonging to the Royal Society, which bears the signatures of both Newton and Halley. It was among the exhibits arranged by the Royal Society for the celebrations on November 30 last.

Newton's name will ever be remembered as the author of the "Philosophiæ Naturalis Principia Mathematica". Nevertheless, it is gratifying to know that, as the result of steps taken by the Royal Society, and through the generosity of the Pilgrim Trust, the Manor House at Woolsthorpe has been secured for posterity as a memorial. A suggestion made by Dr. H. Buckley in a lecture to the Institute of Physics (see p. 731), for a complete edition of Newton's works, is well worthy of consideration. As he pointed out, magnificent editions have been published at the expense of their countries of the works of Galileo, Huygens and Fresnel ; Britain has no such memorial of one who is rightly claimed as the most distinguished of natural philosophers.

NEWTON: SCIENTIST AND MAN

By PROF. S. BRODETSKY

ISAAC NEWTON was born on Christmas Day, 1642; he died on March 20, 1727. His life extended over one of the most significant and exciting periods in British history. When he attended the small village schools near Woolsthorpe in south-west Lincolnshire, Parliament gained its victory over King Charles I. When, as a boy of fifteen, he disappointed his mother's desire that he should administer the modest paternal farm, Cromwell died. When he returned to the Grantham School in order to prepare to go to Cambridge, and was passing through what was his only and unsuccessful romantic episode, the merry monarch King Charles II was restored. The Royal Society was founded when he was a young Fellow of Trinity. When at the age of forty-four his "Principia" was going through the press, he represented the University of Cambridge in its struggle against King James II. He refused to entertain any question of compromise, and approved of the revolution of 1688, for he represented the University as a Whig in the Convention Parliament of 1691. Although he took no part in the debates, for he was a very indifferent speaker and easily embarrassed when expected to make any statement unprepared, he played a considerable part in adjusting the relations between his University and King William III and Queen Mary. It was in the days of Queen Anne that he became the acknowledged representative of English science and received a knighthood. His death in 1727 was followed by the death of King George I, the first of that series of monarchs under whom British democracy was established.

From his graduation in 1665 until March 1696—a period of thirty-one years—Newton devoted himself to a career of scientific discovery which has not been equalled by any other human being. In 1696 he went to London at the invitation of his young Cambridge friend, Charles Montague, who had become Chancellor of the Exchequer, in order to act as Warden of the Mint, and for another thirty-one years he lived in the midst of national affairs. There has been a theory that between his great academic career and his London life Newton had gone through a serious illness involving mental derangement. There is no evidence that his mind was ever affected, although for a time he needed very careful attention.

During the second part of his life Newton retained his full mental vigour, and often carried out difficult mathematical investigations with great success. But it seems that he had lost interest in scientific discovery as such. There is no doubt that the services that Newton rendered to the nation in helping to improve the currency were of considerable importance; but having done this with success and achieved the reward of being appointed Master of the Mint—a semi-gentlemanly position with a large salary and small responsibility—he resigned his chair at the University of Cambridge and was very happy to be the doyen of British science for the remainder of his life.

As a young man Newton possessed two great passions—the love of calculation and the love of experiment. He evidently considered himself to be an experimentalist rather than a theoretical thinker. He devoted very long periods of time to laborious and complicated chemical experiments which led to no serious results. The fact that the man who established the mechanical method on which science has been based for two-and-a-half centuries was so intensely interested in the work of the alchemists of the Middle Ages, and devoted so much attention to the problem of converting base metals into gold, is an interesting illustration of the transition from the science of the Middle Ages to the new era inaugurated by himself: an era of unparalleled triumph in the mechanical interpretation of Nature, the philosophic foundations of which are only being questioned in our own day through the work of Einstein and the new quantum theory, based upon phenomena in the very large and the very small, far beyond any experimental evidence available until more than two centuries after the "Principia" was written.

Newton's aim seems to have been to explain natural phenomena in terms of forces acting on matter, and on the whole he refrained from framing explanations concerning the matter and the forces that he assumed in his work. His famous statement *hypotheses non fingo* was used when he defended himself against Leibniz's accusation that in his law of gravitation he had introduced occult methods into science and taught views contrary to a true belief in God, and really amounted to saying that his task was to explain under what laws things happened in Nature, and that he did not try to deal with the ultimate issues of the universe.

Newton's scientific work consisted of three parts: the optical, the mathematical, and the astronomical. It is scarcely necessary to explain what a remarkable achievement this work represented. It is sufficient to summarize the contents of the "Principia". This is not a text-book of existing knowledge with original additions here and there: it is one of the most original books ever written. The Galileo–Newton laws of mechanics are here formulated for the first time; the mathematical ideas required in the arguments, equivalent to the calculus, without which modern mathematics is unthinkable, are those invented by the author himself; the force of universal gravitation, invoked to explain the heavenly motions, is postulated as the result of Newton's own intuition; the study of fluid motions is initiated in order to dispose of the Cartesian hypothesis of heavenly vortices—the prevalent view held by all scientific men then; the phenomena explained in the "Principia" had never been in any sense satisfactorily explained before; the problems initiated, like lunar theory, planetary theory, shapes of planets, comets, tides, precession, etc., have occupied the best minds of humanity for centuries; the results achieved have been the admiration and inspiration of hundreds of mathematicians and astronomers, and will continue to be so for many centuries to come—and with it all there is a spirit of simplicity, dignity, sanity and soberness, and a grandeur of conception, that place Newton and his work on an unequalled level of eminence.

We are now living in a time when youth is "coming into its own"; often it is misled into hopeless misery. But youth is a characteristic of scientific progress. Einstein once said: "A person who has not made his great contribution to science before the age of thirty will never do so". This was abundantly true of Newton. His three contributions to knowledge—the spectrum, fluxions, and gravitation—were developing when he was a young man of twenty-three. The plague of 1665 drove Newton to his Lincolnshire home, and for a year or two he was more or less cut off from scientific contacts; but many notes made then testify to the growth of these ideas in his mind.

It is unimaginable that one person could have done all that Newton achieved, working alone without help or co-operation from others, interrupting his work by brief and no doubt almost unintelligible lectures, getting his recreation by walking in the little garden that was attached to his rooms at Trinity College, and often spending weeks on futile chemical experiments searching for something in the constitution of matter which he never understood, and which was quite beyond the understanding of those days. Few mathematicians or astronomers have read the "Principia": it is a unique experience to follow Newton's awe-inspiring genius in the original. It is a similar experience to read his "Opticks", and to think that the man who invented these remarkable experiments, leading on by unimpeachable logic to that which laid the foundation of so much of the physics, chemistry, astronomy and technology of the nineteenth and twentieth centuries, was at the same time almost in secrecy evolving new and revolutionary mathematical methods on which he based the "Principia".

Newton had done his work by the time he was forty-four. It is true that he published his "Opticks" when he was sixty-one, but the book largely represented his youthful work. He published later editions of the "Principia", and he made efforts from time to time to deal with lunar theory, but later workers built up systems, planetary and lunar, of which he dreamt. One can easily conceive the whole of Newton's scientific work after the "Principia" eliminated, without in any way affecting the place that he occupies in scientific history.

Newton spent much energy on non-scientific problems. He refused to take Holy Orders in order to retain his fellowship at Trinity, and got special permission from King Charles II to retain his fellowship while remaining a layman. This was not due to light caprice or indifference. Newton was deeply interested in theological philosophy. He had a thorough knowledge of the Bible; he recorded his views about God and Christ, and even attempted to publish—outside England—statements which implied doubts concerning fundamentals of the accepted faith. He was inclined to mystical views. But he was an anti-Catholic and not quite clear about the nature of miracles. He made a very clear distinction between human rights and divine sanction. It was Newton who wrote: "The authority of emperors, kings and princes, is human; the authority of councils, synods, bishops and presbyters, is human; the authority of the prophets is divine". He fought against royal attempts to exercise unlimited authority. He went to Parliament on two occasions as a confirmed Whig, and was a keen opponent of anything which gave to human beings powers that could only be attributed to the divine. It is difficult to compare political views in different periods, but it is not incorrect to suggest that Newton was what we would call to-day an advanced Liberal.

There is a fine streak in Newton's character, showing the immortal scientist behaving with the greatest care and kindness to young men in whom he saw signs of ability or genius. He was especially friendly with Halley, no doubt in gratitude for the way in which Halley carried the financial as well as the editorial responsibilities in the publication of the "Principia"; he was kind and appreciative of Roger Cotes, Colin Maclaurin, James Stirling; he supported the peculiar William Whiston. Newton was very generous even when he was not wealthy. He remained the owner of his small hereditary estate in Lincolnshire, and some of his letters indicate his intense interest in such minor matters as the inhabitability of cottages and the comfort of his tenants.

But Newton's life was spoilt by a series of quarrels with some of the most brilliant men of his time. Even as a young man he could not stand criticism of his scientific work, and announced that he would not publish anything at all if he had to be a "slave to philosophy" and spend his time answering criticisms. It seems that this was why he became an open enemy of that erratic genius Robert Hooke. John Locke described him as "a nice man to deal with", with the Shakespearian meaning of "nice". He had persistent quarrels with John Flamsteed, that brilliant, poor and modest first Astronomer Royal, who had to earn his living as a vicar as well as by private teaching, and who helped Newton with information for the "Principia" and for his efforts on lunar theory. Newton seems to have been a rather unworthy participant in the great controversy with Leibniz and John Bernoulli concerning priority in the discovery of the method of the calculus. These quarrels throw a peculiar light on his personal and scientific character, unworthy of a great thinker. He even wanted to leave the astronomical part of the "Principia" unwritten in case it was subjected to criticism. It seems that in his Cambridge life Newton wanted to be free from all discussion, so as to work privately and uninterruptedly on some things that were useless, and on some which form the glory of human discovery. When he was the public man in London he seemed to possess an extraordinary belief in his own achievements, and treated some other people in a way unworthy of a leader of science.

Newton made some serious mistakes in his scientific work. His optical ideas held up the development of the achromatic telescope, and were an obstacle to the evolution of the wave theory of light. It seems that his primitive theories on fluid resistance kept some people in our own generation dubious of the possibility of flight. Would he himself have disapproved of slavish subservience to his own authority?

One may be doubtful of this, but such was Isaac Newton, endowed with unimaginable mental qualities and with obvious faults; the down-at-heel professional bachelor of his academic days, and the rather wealthy Court favourite of his later years; the man who believed in freedom, who fought the tyranny of a king, and in his own way helped to develop British democracy. Newton was not a statesman or a politician. He was not technically a philosopher. He never recorded any social theory. But it is well to-day to remember him not only as the man who made the heavens intelligible to humanity, but also as a man who helped to give liberty to humanity so that it may be free to look up into heaven.

NEWTON AND THE SCIENCE OF HIS AGE

By Prof. E. N. da C. ANDRADE, F.R.S.

IT is my task—my honourable and inspiring task—to say something of Isaac Newton as seen against the background of the science of his time. I shall try to display briefly the position as he found it and to resume in a small space his great achievements and the changes in outlook which they produced. In praising Newton I shall endeavour to do justice to his great forerunners and to the men of his time who pursued worthily the same great ends as he did, and who would have held the centre of the stage in any other age than that dominated by him. For Newton, like Shakespeare, did not stand as a lonely adventurer into new realms, though he travelled farther and straighter than the rest. Shakespeare was the supreme poet and playwright at a time when poetry and plays were part of the life of every cultivated man and occupied the attention of the brightest intellects. Newton was the supreme scientist in an age when the quantitative method of questioning Nature was abroad in the air. Each was the child of his time.

Let us consider the position when Newton went to Cambridge in 1661. The hold of Aristotle, whose works had for centuries been the ultimate resort of all those seeking knowledge of the working of Nature, had been shaken off by such men as Galileo and Gilbert, but most of the learned still thought that those who relied on experiment were pursuing a futile and impudent course. The first resolve of Marlowe's Faustus

"Having commenc'd, be a divine in shew,
Yet level at the end of every art,
And live and die in Aristotle's works"

still represented the aim of many students. The foundation of the Royal Society in 1662 had been the occasion of many attacks on the experimental method, attacks stoutly met by Glanvill and Sprat, and as late as 1692 Sir William Temple's "Essay upon the Ancient and Modern Learning", satirized by Swift in "The Battle of the Books", set out to prove the superiority of the philosophers of the ancient world over all the moderns. Thus when Newton was a young man the new experimental method of questioning Nature was steadily making its way and the omniscience of the ancients was being called in doubt by a new school, but experimental science was by no means firmly established as a respectable study.

The great figures among the worthies of the exact sciences who had already appeared at that time were Copernicus, Tycho Brahe, Kepler, Gilbert, Galileo and Descartes. Kepler, following his great forerunners, had found the true laws of planetary motion, which were to be explained by Newton. Kepler's views as to the mechanism of the planetary motions were in his earlier writings largely mystical, involving the perfect properties of the five regular solids and also certain motivating souls or spirits. Throughout he held to the medieval point of view that a body could not maintain its motion unless there were a force propelling it. In his later writing he invoked a magnetic force, but it was not directed to the sun, like the true gravitational force, but pushed the planets on their way—"non est attractoria sed promotoria". It was essentially bound up with the rotation of the sun. Thus he was ignorant of the basic laws of mechanics, and his magnetic force had none of the true properties of magnetic forces. Kepler made no approach to a mechanical explanation of his laws. Gilbert had not only established the basic principles of terrestrial magnetism and carried out fundamental work on electricity, but also had invoked a force from the moon—a magnetic force it is true—to produce the tides. Galileo's greatest achievement had been to lay the foundations of mechanics.

None of these men, however, had made any impression on the bulk of the learned: Francis Bacon, for example, does not mention Galileo or Kepler, and refuses to take Gilbert seriously. The great figure in the eye of natural philosophers was Descartes, who had developed a cosmogony based upon mechanical principles, not precise mechanical principles it is true, but principles very different from the mystical ones then in vogue. Joseph Glanvill used to lament that his friends had not sent him to Cambridge, where he might have learned the new philosophy of Descartes, rather than to Oxford, where Aristotelianism ruled. Descartes' system had acquired such a hold on men's minds that his views were still supported long after Newton's death. Both Jean Bernoulli, who died in 1748, and Fontenelle, who died in 1757, were Cartesians to the end. The demolition of the Cartesian system was, in contemporary eyes, one of Newton's greatest achievements. James Thomson said, in his "Ode to the Memory of Sir Isaac Newton", published immediately after his death:

"The heavens are all his own; from the wild rule
Of whirling vortices, and circling spheres,
To their first great simplicity restored..
The schools astonished stood."

From the "Principia" it is clear that Newton himself derived particular satisfaction from having invalidated the Cartesian system. It is fitting, then, that we start our consideration of contemporary science by a glance at this system, not only because it was the only attempt before Newton to explain the motions of heavenly bodies on general principles, but also because it furnishes a contrast which brings out the essential Newtonian point of view.

Descartes starts, in the spirit of medieval thinkers, from certain general philosophical principles. He decides that the fundamental property of matter is extension—impenetrability, colour, hardness and so on are only secondary characteristics. Extension, which has three directions, is the subject of mathematics: motion is the subject of mechanics. All the different qualities of different kinds of matter are provided by different motions of the minute parts of which they are composed. "Give me extension and motion," declares Descartes, "and I will construct the world." One consequence of his fundamental belief is that there cannot be a vacuum, for extension without matter is a contradiction. He further considers, on theological grounds, that the quantity of motion in the heavens must be constant. He blames Galileo for founding his mechanics on experiments and not on reflexions on first causes. "Everything Galileo says about the philosophy of bodies falling in empty space is built without foundation: he ought first to have determined the nature of weight." Newton's point of view, of course, was the exact opposite to that of Descartes: he says in the famous letters to Bentley, ". . . for the cause of gravity is what I do not pretend to know, and therefore would take some time to consider of it"; and again, "gravity must be caused by an agent acting constantly according to certain laws, but whether this agent be material or immaterial, I have left to the consideration of my readers". For Newton, as for the best of his successors, science was concerned with the question of "How ?": Descartes, like the ancients, was concerned with the insoluble question of a fundamental "Why ?".

It followed from the philosophic hypothesis of Descartes that the only kind of motion possible in a plenum was a motion in closed paths, more particularly a circular motion, since a particle could only move if another particle took its place. It was on grounds of this kind that he elaborated his vortex hypothesis. Certain very fine particles, which filled interplanetary space, moved round ceaselessly in huge vortices and carried the planets with them. The moon was carried round the earth by a minor vortex, and so on.

Descartes' cosmogony, then, was founded on a philosophical system: it was pictorial and unquantitative. The paths of the comets handed on from one vortex to another were in particular irreconcilable with observation. There was no attempt to deduce Kepler's laws, or to show how anything but circular motion could result from the vortices. The whole scheme was spun from the brain of Descartes, with more or less casual references to actual phenomena. No doubt it was referring to Descartes that Roger Cotes said in his preface to the second edition of the "Principia", "Those who fetch from hypothesis the foundation on which they build their speculations may form indeed an ingenious romance, but a romance it will still be". In spite of, or perhaps because of, this, Descartes' influence was immense, and when Newton was at Cambridge as a young man it was Descartes who was the great authority for all such as speculated on the structure of the universe.

We now turn to the astonishing story of the birth of the "Principia". The time was ripe for the appearance of this great work. As regards the laws of motion, Galileo, whose services Newton freely acknowledges, and Descartes himself had done much to prepare the way for the more precise and particular formulation which Newton gives. Hooke among others had clearly expressed the protest of the most forward spirits of the time against the speculative method. "The truth is, the Science of Nature has been already too long made only a work of the Brain and the Fancy: it is now high time that it should return to the plainness and soundness of *Observations* on *material* and *obvious* things." The Royal Society was active in stimulating the pursuit of the new method, and on the Continent the Accademia del Cimento had done excellent work, while the Académie des Sciences was founded in 1666. These Continental societies had little influence on Newton, but are symptomatic of the general movement towards the experimental method. The stage was set for great things.

The story opens at Woolsthorpe, Newton's birthplace, whither Newton had come from Cambridge in June 1665 to escape the plague. He was then twenty-two years old and not yet a master of arts or fellow of Trinity. He had read what he calls "Schooten's *Miscellanies*" (probably the "Exercitationum Mathematicarum Libri V"), Descartes' "Geometry" and Wallis' works, and further was, of course, familiar with the work of his teacher Barrow. He had written his first treatise on the calculus, or 'fluxions' as he called it, but he had published nothing. The words which he wrote some fifty years later about this great springtime of his intellectual life have often been quoted but cannot well be omitted on an occasion like this. "In the same year (1666) I began to think of gravity extending to the orb of the moon, and having found out how to estimate the force with which a globe revolving within a sphere presses the surface of the sphere, from Kepler's Rule of the periodical times of the planets being in a sesquialterate proportion of their distance from the centre of their orbs I deduced that the forces which keep the planets in their orbs must [be] reciprocally as the squares of their distances from the centres about which they revolve: and thereby compared the force requisite to keep the moon in her orb with the force of gravity at the surface of the earth, and found them answer pretty near. All this was in the two plague years of 1665 and 1666, for in those days I was in the prime of my age for invention, and minded mathematics and philosophy more than at any time since. What Mr. Huygens has published since about centrifugal forces I suppose he had before me."

It seems likely that he had already his laws of motion in his head—in any case it is clear that he was convinced that every body would continue to move uniformly in a straight line unless some force acted on it, and that, therefore, there must be some force acting on the moon which drew it away from the straight line, tangential at any moment to its path, in the direction of the earth. Treating the moon's path as circular, from Kepler's third law, and from the law connecting the centrifugal force with the radius and the velocity, or the equivalent proposition to which Newton refers, it is easy to deduce the inverse square law. To show that the force keeping the moon in her orbit is the earth's gravitational force, assumed to diminish as the inverse square, is, however, a further step demanding a computation of how strong the gravitational force at the moon's orbit will be, compared to the measured force at the surface of the earth. Newton made this step and found it "answer pretty near". Why, then, did he delay the announcement of the law of gravity for twenty years or so ?

There is always a ready answer to questions of this kind where Newton is concerned—that he never published anything until invited, in general strongly urged, to do so. It is, however, clear from many signs that Newton was not himself satisfied about the matter until some time about 1685. The usual story is that he took a wrong radius for the earth, namely one corresponding to 60 miles for 1° of latitude instead of the correct value of about 70, but this story is very improbable on many grounds, one of which is that good values were readily available to him.

The real reason for Newton putting the work aside seems to have been that the calculation, so far as the force at the earth's surface is concerned, depends essentially upon it being legitimate to assume that the earth's mass may be considered as concentrated at the centre. That this assumption is valid is far from obvious. It is fairly clear from certain passages in "De Motu" and in the "Principia" that it gave Newton some trouble to prove this assumption and that he did it late. In a letter to Halley of June 20, 1686, he says, "I never extended the duplicate proportion lower than to the superficies of the earth, and before a certain demonstration I found the last year, have suspected that it did not reach accurately enough down so low". Although this refers to the gravitational force within a sphere, this and the point under discussion are involved in the same mathematical demonstration, which Newton gives in the "Principia" in Book 1, Proposition LXXI and other propositions following it. In any case Newton appears not to have been satisfied with his first calculations and to have turned to other things, possibly his optical experiments.

It is a strange thing that the "Principia" owes its publication largely to a quarrel with Hooke, and its sequel. In 1679 Hooke, then acting as secretary of the Royal Society, wrote to Newton about various scientific matters and asked him very civilly for a philosophic communication—a paper as we should say nowadays. He also asked for Newton's opinion on his "Potentia Restitutiva" and "particularly if you will let me know your thoughts of that of compounding the celestial motions of the planets of a direct motion by the tangent and an attractive motion towards the central body". In his reply Newton made an extraordinary remark. "But yet my affection to philosophy being worn out, so that I am almost as little concerned about it as one tradesman uses to be about another man's trade or a countryman about learning, I must acknowledge myself averse from spending that time in writing about it which I think I can spend otherwise more to my own content and the good of others: and I hope neither you nor anybody else will blame for this averseness." This is but one of many occasions on which Newton expresses his disinclination, almost distaste, for any further scientific work, his first antipathy having been aroused by the disputes and misunderstandings consequent on the publication of his first great work on the prism.

Nevertheless, Newton did comply with Hooke's request for something for the Society by pointing out that a body let fall from on high should strike the earth slightly east of the perpendicular, and gives precise and excellent directions for following out the experiment. The purpose was to prove the diurnal rotation of the earth. Hooke, in reply, pointed out that the ball should fall to the south as well as to the east, and further corrected Newton in a point which is too complicated to discuss here and one on which differences of statement can be due to different interpretations of the problem. This correction, tactlessly expressed, irritated Newton in the highest degree and he answered curtly. In further letters, written in apparent unconsciousness of the annoyance he had given, Hooke suggested quite explicitly that the law needed to explain the planetary motions was the inverse square law.

Now other men had come to the same conclusion. In particular, Wren and Halley had discussed with Hooke the possibility of explaining the mechanism of the heavens on the basis of an inverse square law. Hooke declared that he could demonstrate mathematically that the path of a particle in a central inverse square field would be an ellipse, but it is clear that he never did so, and equally clear that he had not the mathematical equipment necessary to begin an attack on the problem. He was in the unfortunate position of being entirely convinced of a truth that he could not prove. In August 1684 Halley visited Cambridge and asked Newton what the path would be. He replied that it would be an ellipse and that he had formerly calculated it. He could not find the calculation but soon sent a proof (or apparently two different proofs) to Halley.

This incident seems to have aroused Newton from the distaste for science into which he had fallen, and he put together the treatise "De Motu", founded on a course of lectures, which Halley presented to the Royal Society on December 10, 1684. The story of how Halley then coaxed and cajoled Newton into writing the "Principia" is familiar, but we in the Royal Society ought never to celebrate the great work without a tribute to Halley, who not only realized at once the fundamental importance and significance of Newton's work but also used all his tact to get the book written and made himself financially responsible for the production, the Royal Society being in financial difficulties at that time. We are not now in financial straits and shall, I believe, be glad to bear the expense of producing a second "Principia" when the genius of our age brings it forth. The book appeared in 1687, and bears the imprimatur of the then president, who, although he achieved nothing in science, is still remembered. He was Samuel Pepys.

The "Principia" is not an easy book to read. The proofs are all given in the form of classical geometry, although, since it is certain that at the time when it was written Newton was in possession of the fundamental processes of the calculus and of the methods of analytical geometry, it is unlikely that this was the form in which he first derived them. Whewell has said, "Nobody since Newton has been able to use geometrical methods to the same extent for the like purposes; and as we read the 'Principia' we feel as when we are in an ancient armoury where the weapons are of gigantic size; and as we look at them we marvel what manner of man he was who could use as a weapon what we can scarcely lift as a burden". Various conjectures have been made by Rosenberger, Cantor, Giesel, Gerhardt and others as to why he did not use the new methods: Rouse Ball thinks that he was probably unwilling to add to the difficulties by introducing a new mathematical method. Be that as it may, he had a horror of unfounded criticism, and, as he told Dr. Derham, "to avoid being baited by little smatterers in mathematics, he designedly made his 'Principia' abstruse; but yet so as to be understood by able mathematicians". That he did not underrate the difficulty of the work is clear from what he says in the beginning of Book III: "I chose to reduce the substance of that book into the form of propositions (in the mathematical way) which should be read by those only, who had first made themselves masters of the principles establish'd in the preceding books. Nor would I advise any one to the previous study of every proposition of those books. For they abound with such as might cost too much time, even to readers of good mathematical learning. It is enough if one carefully reads the definitions, the laws of motion, and the first three sections of the first book."

The first book contains certain definitions of space, mass and time which have afforded the more metaphysically inclined a theme ample enough for discussion. But we will here let them pass uncommented. The famous laws of motion owe much to the labours of previous workers, in particular to Galileo, whose services Newton clearly acknowledges. The simple laws of central orbits under an inverse square law are worked out in much detail and the laws of pendulum motion are developed, with due acknowledgments to Huygens, who had published his "Horologium Oscillatorium" in 1673.

In the first book the motions are all supposed to take place in a non-resistant medium. In the second Newton considers motions in a resisting medium, always with his eye on the Cartesian world system which he was intent to demolish. He deals with a resistance proportional to the velocity and a resistance proportional to the square of the velocity, and further points out different kinds of fluid resistance, which he later defines most clearly in the 28th Query appended to the third edition of the "Opticks", "for the resisting Power of the fluid Medium arises partly from the Attrition of the Parts of the Medium and partly from the *Vis inertiae* of the Matter", that is, partly from the viscosity and partly from the bulk motion of the medium. The latter resistance he assumes proportional to the square of the velocity. In this book he opens the way to the hydrodynamics of real fluids. In the part dealing with hydrostatics he proves the law of the diminution of atmospheric pressure with height. He then discusses the motion of the pendulum and is the first to suggest its use for making a survey of the gravitational acceleration. In another connexion he derives an expression for the velocity of sound, this being the first case of a calculation of the velocity of a wave from the properties of the medium. The only other point in this book to which I will refer is the calculation which Newton carries out on the motion of an infinitely extended viscous fluid in which a body rotating upon its axis is immersed. What he has in mind is the Cartesian vortex—"I have endeavoured in this proposition to investigate the properties of vortices, that I may find whether a celestial phenomenon can be explained by them". He effectively defined the force "arising from the want of lubricity in the parts of the fluid" as proportional to the velocity gradient, whence the term 'Newtonian viscosity'. He is thus the first to touch the mathematics of viscous fluids. He finds that the periodic time of circulation of the fluid carried round by the rotating sphere is proportional to the square of the distance from the centre of the sphere*, which is grossly inconsistent with Kepler's third law. Newton considers that his deduction is a clear refutation of the Cartesian vortices and, for once, almost gloats over his victory. "Let philosophers then see how the phenomenon of the sesquialterate ratio can be accounted for by vortices". He brings many other objections against the Cartesian vortices: he points out, for example, that a continuous supply of energy will have to be given to the sphere to maintain the motion, because "it is plain that the motion is proportionally transferred from the centre to the circumference of the vortex, till it is quite swallowed up and lost in the boundless extent of that circumference".

The second book of the "Principia" is the foundation stone of mathematical physics. In it Newton shows an extraordinary instinct for grasping the essentials of a problem—it would almost seem that he knew the solution in advance and added the proof as a concession to those less clear-sighted. The manner of his refutation of the Cartesian vortices introduces a new spirit into the discussion: no hypothesis about the heavens is tenable unless the quantitative deductions from it agree with observations.

The third book opens with an introduction where, after stating what has been done in the first two books, Newton sets down the superb sentence, "Superstat ut ex iisdem principiis doceamus constitutionem systematis mundani"—it remains that from the same principles we demonstrate the form of the system of the world. It is this third book which based celestial mechanics so firmly that what was done in the next two hundred years was rather extension of, and improvements on, the Newtonian method than anything radically new. Not only does Newton establish the movements of the satellites of Jupiter, Saturn and the earth, and of the planets round the sun (or rather, as he points out, round the centre of gravity of the solar system) in terms of his gravitational theory, but also he shows how to find the masses of the sun and planets in terms of the earth's mass, which he estimates quite closely to the present accepted value; he accounts for the flattened shape of the earth and other planets; calculates the general variations of g over the surface of the earth; explains the precession of the equinoxes by consideration of the non-sphericity of the earth; calculates the main irregularities of the motion of the moon and of other satellites from the perturbing effect of the sun; explains the general features of the tides; and finally treats the orbits of comets in a way that showed that they were members of the solar system and enabled the return of Halley's comet in 1759 to be accurately calculated. This brief and imperfect catalogue is merely a reminder of the scope of this extraordinary book, which drew from Laplace, no enthusiast, ". . . all this, presented with much elegance, assures to the 'Principia' preeminence over all the other productions of the human mind". The book closes with the famous general scholium which returns to the confutation of Descartes' vortices and says, concerning the cause of gravity, "Hypotheses non fingo".

Although the book was eagerly bought, the Newtonian method and discoveries made way but slowly. Biot says that of Newton's contemporaries three or four only were capable of understanding the "Principia", that Huygens only half adopted the ideas, Leibniz and Jean Bernoulli fought against them, and that fifty years had to pass before the great truth demonstrated by Newton was understood by the generality of men of science, let alone developed. No doubt the difficulty of the book had much to do with the tardy appreciation, outside a narrow circle, of its contents. The Cartesian scheme was easy, pictorial, general: the Newtonian difficult, mathematical, precise. The very method of attacking the problem was altogether new. The second edition appeared in 1713, edited by Roger Cotes, of whom Newton said, "if Mr. Cotes had lived we might have known something". The preface clearly shows that among the learned the Newtonian scheme had not been widely accepted. On the Continent the progress was still slower and it is generally held that it was Voltaire's "Elémens de la Philosophie de Neuton", which appeared in 1738, that led to Newton's work being appreciated in France. Incidentally, the story of the apple, which Voltaire had from Newton's niece, Mrs. Conduitt, first appeared in the second edition of Voltaire's book, in 1741. Later, it was in France that Newton's work was raised to great glory, when Lagrange and Laplace erected edifices of splendour and elegance on Newtonian foundations.

---

* Actually this is an error, which appears never to have been pointed out, although Stokes has indicated the like error in the case of the rotating cylinder, which Newton works out. It should be the *cube* of the distance.

The optical work of Newton was perhaps his favourite study: at any rate it was that to which he gave what is probably the only enthusiastic reference which he ever permitted himself, when he said, of his fundamental discovery in the matter of prismatic colours, "being in my judgment the oddest, if not the most considerable detection which hath hitherto been made in the operations of nature". I do not propose to say anything of the beautiful experiments which form the backbone of the book, but a few words as to the Newtonian attitude to the theoretical aspect may be permitted.

The nature of colour had from the days of Aristotle been the subject of philosophical speculation. According to Aristotle, colours are a mixture of light and darkness, or of white and black, a view which, embellished and modified in various ways, survived Newton and appeared again in, for example, Goethe's writings. Descartes was apparently the first to break really new ground in comparing colours to notes in music: his view of light was that it was a pressure transmitted through the particles that filled all space, and he conjectured that a rotation of the particles might be the effective cause of colour, a view which presents inherent difficulties effectively exposed by Hooke. We may agree with Huygens that "Descartes has said nothing that is not full of difficulties or even inconceivable, in dealing with light and its properties". The medieval question as to whether light was a substance or an accident was still occupying the attention of even acute experimentalists such as Grimaldi, the discoverer of diffraction, whose book appeared in 1665. It was Hooke again, who, with his extraordinary flair for the truth, combined with an inability to overcome the last difficulties that stood between him and a convincing conclusion, initiated the modern views. In his "Micrographia", 1665, he expressed the view that light was a very quick vibration propagated with a finite velocity. He gave what is something like Huygens' construction for finding the wave front on refraction, but, since he thought that light travelled faster in a solid medium, such as glass, than in air, he found that in the medium the wave front must make an acute angle with the ray. It was with this 'obliquity' that he connected colour. "Blue is an impression on the Retina of an oblique and confus'd pulse of light, whose weakest part precedes, and whose strongest follows. . . . Red is an impression on the Retina of an oblique and confus'd pulse of light, whose strongest part precedes and whose weakest follows." For him blue and red were the primary colours, all others being mixed. There is no time to follow his extraordinarily acute experiments on the colours of thin plates, but it must be noted that his ill-tempered attacks were the cause of Newton expressing a disgust with science which nearly caused him to abandon her pursuit, and were, it is almost certain, the reason why the "Opticks" was not published until 1704, the year following Hooke's death. The quarrel between the two men, both, as is evident from their correspondence, capable of generous appreciation of the other's achievements, was exacerbated by Oldenberg, then secretary of the Royal Society, whose dislike of Hooke may have sprung from causes little creditable to him. Newton had been undoubtedly stimulated by his reading of Hooke's "Micrographia", and he was always very remiss in acknowledgments to him. Let us pay a tribute to poor Hooke, sickly and without position or powerful friends. He had not Newton's power of thought, but he was probably the most ingenious contriver who ever lived and was a shrewd and daring speculator.

Nowhere more than in his writings on light does Newton stress his dislike of speculation not firmly rooted in experiment. The first words of the "Opticks" are "My design in this Book is not to explain the Properties of Light by Hypotheses, but to propose and prove them by Reason and Experiments", and again, in the 31st Query appended to the third edition of that book, he makes his point of view very clear, saying "These Principles I consider not as occult Qualities, supposed to result from the specifick Forms of Things, but as general Laws of Nature, by which the Things themselves are form'd: their Truth appearing to us by Phaenomena, though their Causes be not yet discover'd. For these are manifest Qualities, and their Causes only are occult. And the *Aristotelians* gave the Name of occult Qualities not to manifest Qualities, but to such Qualities only as they supposed to lie hid in Bodies, and to be the unknown Causes of manifest Effects. . . . To tell us that every Species of Things is endow'd with an occult specifick Quality by which it acts and produces manifest Effects, is to tell us nothing." It is in the light of this that we must read the famous "Hypotheses non fingo". Newton, of course, did make hypotheses, and even called them such—for example, in "Principia", Book II, Section IX, his assumption as to the behaviour of viscous fluids is headed "Hypothesis", and there are other instances. All he meant was that he was reluctant to speculate beyond any possibility of quantitative deduction, to form conjectures the defence of which would be merely a matter of dialectics.

Newton's corpuscular hypothesis to account for the experimental behaviour of light is clearly a hypothesis, but we shall see how closely he adapts it to the observations. First, he points out that light cannot be a wave motion, or it would spread out on passing through an opening. He knew, it is true, the phenomena of diffraction, but he did not realize how by making the wave-length small enough this could be reconciled with the general facts of rectilinear propagation, for which a stream of particles seems best suited. He clearly saw that the phenomena of the colours of thin plates demanded a periodicity, and he introduced this into his theory by the hypothesis of fits of easy reflexion and easy transmission. It is clear that light is partly reflected and partly transmitted at the surface of a transparent body: Newton supposed that a light particle alternated at regular intervals between a state in which it was transmitted through the surface and one in which it was sent back. He put forward diffidently ("Those that are averse to assenting to any new Discoveries but such as they can explain by an Hypothesis, may for the present suppose . . .") the idea that the impact of the particle on the surface excited vibrations in the medium which, overtaking the particles, put them into these alternating states. We are forcibly reminded of modern theories. The length of the interval of the fit, corresponding to our wave-length, was greater for the red than for the blue, and Newton gives the interval for yellow light incident normally as just about the actual wave-length of yellow light. Unfortunately, the length of the fit depended on the angle of incidence. However, of his whole theory he says, "But whether this hypothesis be true or false I do not here consider. I content myself with the bare Discovery that the Rays of Light are by some cause or other alternately disposed to be reflected or refracted for many vicissitudes". When he comes to consider polarization, he has to endow his particles with 'sides', so that there was a lack of complete symmetry about the direction of propagation. In short, he gave his particles just those properties which interpreted the experiments and hence was led to endow them with a periodicity and a polarity. This brought him to assume subsidiary waves accompanying the particles when they interacted with matter.

There seems to be a general belief that Huygens, as against Newton, advocated something very close to the wave theory of light, as it was accepted in, let us say, 1900. Huygens' wavelets, however, lacked the essential properties with which Fresnel afterwards endowed them: they were not only longitudinal but also had what are practically particle properties, as exemplified by the fact that the pole, the place where the wavelet touches the envelope, alone is efficacious. He was just as incapable as Newton of giving a satisfactory explanation of diffraction.

If we are asked to state in a sentence what was the main effect of Newton's work on the thought of his time, I think that the answer must be that it was to establish the power and universality of the methods of quantitative science. To Galileo we owe the great service, one that cannot be too highly praised, of having made particle dynamics into a science, but he did not look beyond the earth for its efficacy or suggest the application of his methods to the relative movement of the parts of a continuous medium, such as water. Huygens founded the study of rigid dynamics. Hooke suggested and speculated with extraordinary ingenuity and acuteness. Newton, however, showed that three clearly enunciated laws of motion applied to all observable movements of inanimate Nature: they governed the motion of waves and projectiles, visible solids and invisible air, resisted as well as free movements. Together with the inverse square law they explained not only the gross movement of planets and the movement of the comets, which before had seemed capricious, but also details which nobody had ever considered as being mechanically explicable, such as the precession of the equinoxes. The problems of the tides and of the irregularities of the moon's motion he did not fully solve, it is true, but he did enough to convince mathematicians that they were soluble by his methods. After Newton's work had been assimilated, the body of natural philosophers accepted it as a commonplace that all terrestrial and celestial movements were explicable in precise and numerical terms by calculations based on a few general laws: before Newton most thinkers were ready to invoke *ad hoc* principles and occult causes, based on human and divine analogies, for any but the simplest terrestrial phenomena, and the few who were in advance of their times were feeling tentatively for solutions which eluded their grasp.

Even in such thoughts on chemistry as he published Newton was looking for an explanation in terms of attractions, though, strangely enough, in this science he never seems to have applied his own rule and made quantitative experiments. His work on light lies somewhat outside the mechanical scheme, but here again his insistence on the quantitative created a completely new attitude towards colour. It became a subject for measurement and calculation, rather than one for discussion in terms of generalities.

If we are to try to represent Newton's achievements by some modern analogy, to construct some imaginary figure who should be to our times what Newton was to his, we must credit this synthetic representative with, I think, the whole of relativity up to, and somewhat farther than, the stage at present reached—we must suppose our modern Newton to have satisfactorily completed a unitary field theory. In light we must credit him both with having established the existence of spectral regularities and with their explanation in terms of the quantum theory. Possibly, too, we must give him the Rutherford atom model and its theoretical development, a simple astronomy in little to correspond to the solar system. Let us, then, think of one man who, starting in 1900, say, had done the fundamental work of Einstein, Planck, Bohr and Schrödinger, and much of that of Rutherford, Alfred Fowler and Paschen, say, by 1930, and had then become governor of the Bank of England, besides writing two books of Hibbert Lectures and spending much of his time on psychical research, to correspond with Newton's theological and mystical interests. Let such a man represent our modern Newton and think how we should regard him. Only so, I think, can we see Newton as he appeared to his contemporaries at the end of his life.

There are no discontinuities in Nature and there are none in the history of science. No discovery or fundamental innovation is absolutely new, unconnected with past thought and the stirring spirit of its own time. Newton was not uninfluenced by certain of his immediate predecessors and of his contemporaries. The revolt from the introspective method of constructing explanations of heavenly and earthly phenomena by appeals to philosophic necessity had begun before his birth, and his time was rich in brilliant exponents of the experimental philosophy, whose names will always stand as stars adorning the story of science. To compare him with other men of his time and to recognize their contributions to the development of the physical sciences does not, however, lead us to think less of Newton's achievements but rather to wonder at them all the more. It is easier to estimate the size of a Colossus if there are statues of more than life size in its neighbourhood than if it stand alone in a desert.

Newton owed much to the pioneer labours of Galileo, who had founded the science of mechanics, and, in a different way, much to Barrow, whose great mathematical acuteness and sympathetic support were always at the disposal of the young Cambridge scholar. To Hooke he owed more than he was ever prepared to acknowledge. From his great Continental contemporaries, Huygens and Leibniz, he borrowed little, if anything. Possibly if mathematical advances were alone in question Leibniz would have to be considered for a place on the same level as Newton, but for Newton mathematics were merely a means to a physical end: his mathematical innovations may even be left out of consideration without grave injury to Newton's fame. There is no record of physical experimentation that can compare for mastery and elegance with the "Opticks", no work in exact science that produces the same impression of supreme greatness and power of thought that the "Principia" does.

The spirit of this age is a denigrating one, which, in a reaction from the earlier custom of representing great men as free from all blemish and weakness, delights in attempting to show that nobody much exceeds the common level. If an earlier painter might have left out Cromwell's warts, the painter of to-day might represent his face as one huge wart. I have read records of Newton's weaknesses and I know of the adumbrations of his discoveries that can be found in forerunners and contemporaries: I acknowledge that his earlier biographer shut his eyes to any incident, writing or action that might seem to detract from his perfection. Nevertheless, all things considered, I think that the contemporary judgment of his greatness can still stand, and that, if the Marquis de l'Hôpital's query as to whether Newton ate, drank or slept like ordinary men ("for I picture him to myself as a celestial genius") seems to our present-day sobriety an affectation, nevertheless we may agree that the line of Lucretius placed on the Trinity statue was well chosen and fitting—

> Qui genus humanum ingenio superavit
>
> "who excelled the human race in power of thought".

NEWTON AS AN EXPERIMENTER

By THE RIGHT HON. LORD RAYLEIGH, F.R.S.

THE duty has been assigned to me of telling you something about Newton as an experimentalist. As the result of a study of what is known of his history, it seems to me that among his various intellectual pursuits experiment was his first love and the love to which he was most constant. Strange though it be, he seems in some moods to have doubted whether his theoretical studies were worth while, and I do not recall any case where he expressed himself enthusiastically about them. On the other hand, he speaks of his optical work as "The oddest, if not the most considerable detection which hath hitherto been made in the operation of nature".

Newton loved the mechanical side of experimental work. As a boy he constructed sundials, and, what is more, fixed one of them into the side of the house effectually enough for it to be there a century later. A notebook of his boyhood shows him assiduous in collecting recipes for various kinds of drawing materials, and he notes methods of performing some (rather nasty) conjuring tricks. Later on, when he is making his reflecting telescope, it is obvious that he is a skilled amateur mechanic, at home in furnace operation. He builds his own brick furnace, prepares speculum metal, and is apparently more successful than the professional opticians of the time in grinding and polishing it to a satisfactory spherical figure. (The days of parabolizing were not yet.) It was not until a good many years later that they were able to put such instruments on the market.*

Asked in his old age where he got the tools for his work, he replied that he had made them himself, and could have achieved little progress without doing so.

There are occasional hints to be gleaned that Newton practised other mechanical arts. Thus, when he examines the colour of thin blown glass, it appears that he has the facilities for glass-blowing at hand, and was presumably able to use them.

So much for the base mechanical side. Newton, however, had what may be called the itch of experiment and instinctively examined in this way any natural phenomenon that excited his interest. This instinct is not a common one, and it would be of interest to investigate statistically whether it is more correlated with mathematical aptitude than with, say, an aptitude for literary and historical studies. Newton had all these. Although he experimented in other fields, such as mechanics, heat and electricity, and even in anatomy and physiology, his optical experiments are of much greater importance, and in the short time at our disposal we shall only be able to consider a part even of these. The fundamental researches on the composition of white light were read before the Royal Society in 1672, and afterwards recapitulated in his "Opticks" (1704), and we cannot do better than concentrate our attention on them. Although the results are common property nowadays, yet on an occasion like this we shall do well to go back to Newton's own methods and point of view, and to repeat his experiments as nearly as we can in his own way. We must be content to use the positive crater of the electric arc to represent the sun.

Newton's experiments on the spectrum are sometimes presented as if he had started out with the idea of examining the composition of white light. It is true that his "Opticks" (like his "Principia") introduces the various topics as theorems or problems proposed after the manner of Euclid. It does not seem likely, however, that he set out in the first instance to prove any proposition. He bought a prism at Stourbridge Fair (near Cambridge) in 1666, "to try therewith the celebrated phenomena of colours". It is clear from this that the prismatic colours were quite a well-recognized phenomenon at this time, and this is also shown by the circumstance that the art of cutting diamonds so as to display them was already long known. In Peacham's "Gentlemanly Exercises" (1612) reference is made to "A three square cristal prisme wherein you shall perceive the blew to be outmost next to the red", and Grimaldi and others had already experimented on the subject, though without arriving at clear views. We can readily imagine how Newton, handling the prism, would soon find that the colours were well seen in candle-light, but not in diffused daylight. It would not be a long step from this to try the effect on a beam of direct sunlight admitted through a hole in the shutter.

There is no reason to think that he did this with a very clear anticipation of what the effect would be. He was exploring a nearly virgin territory. His beam of sunlight passing through the hole produced an image of the sun. It was what we now call a pinhole image, though the hole need not be very small. Newton's hole was $\frac{1}{3}$ in. diameter. Then he interposed the prism (Fig. 1).

To most people the colours would seem the main

---

* Among the first successful commercial makers of reflecting telescopes was James Short (1710–1768), whose instruments were of the Gregorian type. He is said to have made a considerable number of concave and convex mirrors, and to have 'married' them by trial of what pairs gave the best result.

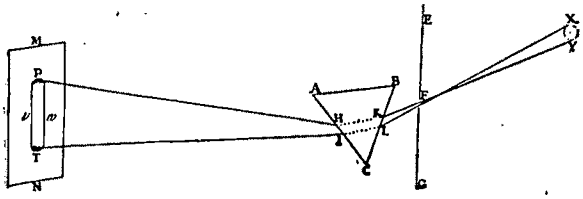

Fig. 1.

feature of this experiment, but Newton was more surprised and impressed with the fact that the sun's image was no longer round, but was spread out into a band of which the length was some five times the breadth. The breadth of the image as projected through the prism still answered to the sun's diameter, that is to say, it was equal to the diameter of the original round image of the sun at the same distance with the prism away.

"If," he says, "the refraction were done regularly according to one certain proportion of the sines of incidence and refraction, as is vulgarly supposed, the refracted image ought to have appeared round."

At the same time the colours had to be taken into account. Were the colours definitely related to the differences of refraction, or was the apparent relation only incidental? In Newton's words:

"Wherever this inequality arises, whether it be that some of the incident rays are refracted more, and others less, constantly or by chance, or that one and the same ray is by refraction disturbed, shattered, dilated and as it were split and spread into many diverging rays, as Grimaldi supposes, does not yet appear by these experiments, but will appear by those that follow."

The next experiment was accordingly designed to throw light on this point. It is known as the experiment of crossed spectra (Fig. 2), the idea being to refract each of the coloured rays a second time, in a direction at right angles to the former, and to see whether the blue rays, which were more refracted than the red, would be so again. Also to see whether they would retain their original colour, or whether they would undergo further analysis.

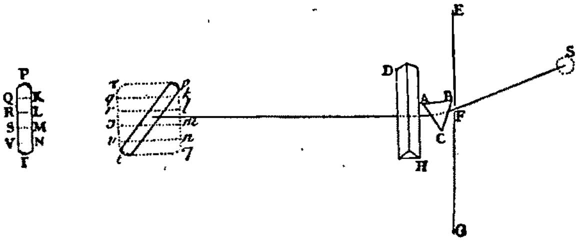

Fig. 2.

Newton made several more elaborate variants of this experiment. In one of them, two holes were used with a prism in front of each, and two spectra were then projected on the screen in line, the red of one following on the blue of the other. Refracting them upwards with a third prism, this line is dislocated, and that blue and red which were before adjacent are now widely separated (Fig. 3).

Newton in this way arrived at the view that the original white light of the sun consisted of coloured components, red, yellow, green, blue and violet. Each of these had a characteristic index of refraction and was bent to a perceptibly different extent by the prism. The result was that the original round white image of the sun was replaced by a series of coloured images side by side, overlapping and blending one with another. On introducing a second prism at right angles, each of these coloured images was again refracted to its characteristic extent and each retained its colour without further analysis.

Newton, however, soon saw the crudeness of his first arrangements, and we will now consider the methods he used to improve them. As he pointed out, the individual coloured images of the sun overlap at the middle, but not at the edges. Images of the sun are not in fact very suitable, because the angular width of the sun is about half a degree, and this is a considerable fraction of the angle between the red and violet rays. We want to make the sun in effect smaller, by blocking out part of its disk, which might be done in imagination by a distant diaphragm supported in mid-air. At the same time the hole in the shutter might with advantage be replaced by a lens, which would render the images sharper. When we have got so far in imagination, we notice that the long distance between the diaphragm in mid-air and the lens is not essential; with a suitable lens a moderate distance will do. We bring the diaphragm nearer, and fix it in the shutter, and bring the lens forward into the room, placing it so as to form a distinct picture of the diaphragm on the wall (Fig. 4).

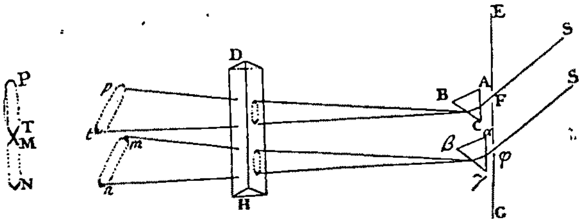

Fig. 3.

We have now the diaphragm fixed in the shutter, and backed by the sun, as our effective source of light. In this respect it differs altogether from the original diaphragm, which acted not as a source, but as an image-forming pinhole. We now have a picture of the diaphragm and not of the sun, and it will be advantageous to substitute a slit, which would not previously have been any use, because the size of the image was then defined by the angular diameter of the sun. With the slit *and the lens* we shall get narrow well-defined images in each colour, and the colours will be pure and not overlapping. (Needless to say, modern refinements carry the matter much further.)

The explanation I have just given is in substance Newton's own.

Let us now project the spectrum on to a small

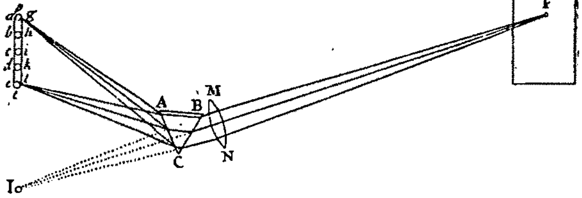

Fig. 4.

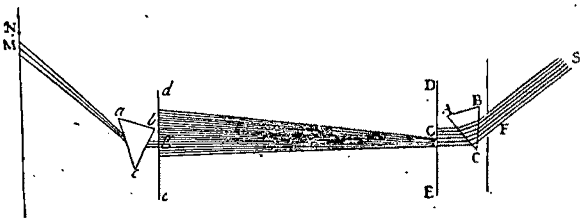

Fig. 5.

screen with a slit (Fig. 5) in it, which to avoid confusion I will call the screen-aperture. A colour passing through the screen-aperture is isolated, and if I rotate the prism, I can throw the various colours in succession on the slit in the screen-aperture, so that the image on a second screen is taken through the succession of spectrum colours from red to violet. Starting with it at the red, and placing a second prism in position behind the screen-aperture, the rays are deviated, as we should expect ; but there is no elongation of the image this time, nor is there any diversity of colour. The red image remains red. The same applies to any other colour of the spectrum that is passed through the screen-aperture. But as the successive colours are passed, from red to violet, the deviation on the second screen continually increases, the red being the least deviated and the violet the most.

This experiment shows essentially the same thing as the experiment of crossed spectra, but more perfectly.

The important point is that having once analysed white light into its prismatic constituent colours, this analysis is final, and further prismatic analyses can do no more. Further, each colour has its characteristic refrangibility, which will show itself at every refraction. Newton attached the greatest importance to this experiment, which he called, in Baconian phrase, the "experimentum crucis".

Having effected the analysis of white light into its constituent colours, he proceeded to reverse the process, and to show how the colours of the spectrum could be recompounded into white light. This he did by projecting the spectrum upon a large lens (Fig. 6), when the various rays were all converged to the same place and produced a patch of white light at the focus.

If a kind of large-scale model of a comb as used by Newton (Fig. 7) be placed in front of the lens, some part of the spectrum will be intercepted by the comb, and the white patch produced at the focus of the lens by recombination of the entire spectrum loses its whiteness, and becomes tinged with colour. The colours produced in this way are not pure spectrum colours, because any tooth of the comb permits colour from parts of the spectrum on either side of it to pass. The colours therefore are composite, but the complete spectrum is necessary to produce white. If the comb is moved slowly to and fro, the coloured patch varies, being now reddish, now yellowish, now bluish, but never white. If, however, it is moved to and fro as rapidly as may be, all the spectrum colours are present in succession. They blend by persistence of vision, and the patch becomes white again.

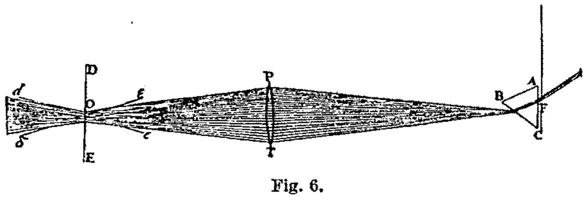

Fig. 6.

Newton devoted considerable attention to the colours of natural bodies, and he came to the conclusion that a coloured body is only coloured in virtue of its power of reflecting some of the components of white light more than others. When a spectrum is projected on a red screen, we see red light where we saw it before, and nowhere else. The colours are not altered, though red is the only one which is strongly reflected by the red screen. The others are mostly absorbed, and their place in the spectrum is comparatively dark. Red is advantageous for such experiments, as red pigments are much the purest in colour.

In another of Newton's experiments the spectrum is projected on a large lens as before. If a white card is held at the focus, it appears white, for all the colours are converged upon it. If a card painted with cinnabar (vermilion) is placed there, it appears red as usual. If we block out the red part of the spectrum at the lens, the card shows no trace of red, becoming comparatively dark. If we block out everything but red, the card shows up with a purer red than at first.

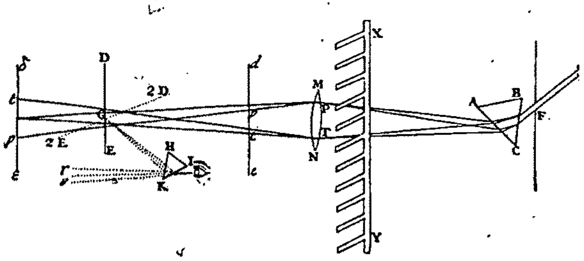

Fig. 7.

We have now been through most of the experiments by which Newton supported his main proposition "The light of the sun consists of rays differently Refrangible", following his own methods as closely as might be. They are a model for all time of how experimental research should be conducted, and it is difficult to our generation to see how any intelligent person could refuse his assent. This was by no means the unanimous opinion of his own contemporaries. One critic, Linus by name, maintained that the spectrum could only be seen when the sun was shining through cloud, and it is strange, but true, that Newton was seriously discomposed by this ridiculous mare's nest. Goethe bitterly attacked Newton, using abusive expressions, and apparently thinking that to use isolated beams of sunlight admitted into a dark room was treating Nature in an unfair manner, and compelling her under torture to say what she did not really mean !

The opposition to Newton's views did not finally die down until within measurable distance of our own time. In a book dated 1853, and dedicated to a man whom I as a boy personally knew, Sir David Brewster says : "The conclusion deduced by Newton is no longer admissible as a general truth 'That to the same degree of refrangibility ever belongs the same colour and to the same colour ever belongs the same degree of refrangibility'."*

* It is not intended to criticize Brewster adversely. The appearances by which he was misled are extremely deceptive.

Let us not make the mistake of thinking that Newton in his optical researches, exploring virgin ground, had easy triumphs. He did not escape the usual fate of discoverers. His jealous contemporary Hooke said his conclusions were not new; his admiring biographer, Brewster, concluded that they were not true!

Exhibits Illustrating some of Newton's Experiments

Arranged by Lord Rayleigh, as a supplement to those shown in his lecture.

"OPTICKS." BOOK I. EXPERIMENT I.

To show that lights which differ in colour differ also in refrangibility.

Newton's account abbreviated:

"I took a black oblong stiff paper. One part I painted into a red Colour, the other into a blew. This paper I viewed through a Prism of Solid Glass. I found that if the refracting Angle of the Prism be turned upwards so that the paper may seem to be lifted upwards by the Refraction, its blew half will be lifted higher by the Refraction than its red half. But if the refracting Angle of the Prism be turned downwards, so that the Paper may seem to be carried lower by the Refraction, its blew half will be carried something lower than its red half."

A.—"OPTICKS." BOOK I. PART II. EXPERIMENT XVI.

In this experiment a uniform field of light is viewed through a reflecting prism. Newton used the cloudy sky. An illuminated opal glass is substituted. The bright part of the field is the region of total reflexion. The relatively dark part of the field, corresponding to steeper angles of incidence, is the region of partial transmission and partial reflexion. A blue arc marks the limit of total reflexion. This shows that white light contains a constituent (blue) which begins to be totally reflected at angles of incidence less steep than are necessary for the other components.

"This blue colour being made by nothing else than by reflexion of a specular superficies seems so odd a Phenomenon, and so unaccountable for by the vulgar Hypothesis of Philosophers that I could not but think it deserved to be taken notice of."

B.—A supplement was arranged to this exhibit, allowing the transmitted light to be examined. A pair of right-angled prisms is used, forming a cube after the manner of Newton, reflexion occurring at the diagonal interface. The field is divided into a bright and a dark part as before, the dark part (no transmission) being the area of total reflexion. A reddish-yellow arc marks the limit of transmission, which is complementary to the blue arc seen by reflexion.

This experiment was performed by Newton in a more elaborate way, using the sun's light and projecting a spectrum of the beam transmitted by the cube.

"OPTICKS". BOOK II. PART I. OBSERVATION xiii.

An experiment showing that Newton's rings, formed between a spherical surface of large radius and a flat plate, are larger in red light than in blue. The observer can rotate the spectrum-forming prism and see the rings dilating as the colour is changed from blue or blue-green towards red.

"Appointing an assistant to move the Prism to and fro about its Axis, that all the Colours might successively fall on that part of the Paper which I saw by reflexion from that part of the Glasses where the Circles appeared, so that all the Colours might be successively reflected from the Circles to my Eye whilst I held it immoveable, I found the Circles which the red light made to be manifestly bigger than those which were made by the blue and violet. And it was very pleasant to see them gradually swell or contract according as the Colour of the Light was changed."

Newton recognized that this proved that there was a coarser structure associated with red light than with blue. In Query 13 at the end he says:

"Do not several sorts of rays make vibrations of several bignesses, which according to their bignesses excite sensations of several colours?"

AN EXPERIMENT ON FRICTIONAL ELECTRIFICATION.

From the Minutes of the Royal Society. 9 *December* 1675.

"That [Newton] having laid upon a table a round piece of glass about two inches broad, in a brass ring, so that the glass might be about one-third of an inch from the table, and the air between them inclosed upon all sides after the manner as if he had whelved a little sieve upon the table: and then rubbing the glass briskly, till some little fragments of paper, laid on the table under the glass, began to be attracted and move nimbly to and fro; after he had done rubbing the glass, the papers would continue a pretty while in various motions; sometimes leaping up to the glass and resting there awhile; then leaping down and resting there, and then leaping up and down again; and this sometimes in lines perpendicular to the table sometimes in oblique ones; sometimes also leaping up in one arch and down in another divers times together, without sensible resting between; sometimes skip in a bow from one part of the glass to another, without touching the table; and sometimes hang by a corner and turn often about very nimbly, as if they had been carried about in the midst of a whirlwind; and he otherwise variously moved every paper with a diverse motion. And upon sliding his finger on the upper side of the glass, though neither the glass nor inclosed air below were moved thereby, yet would the papers, as they hung under the glass receive some new motion inclining this or that way, according as he moved his finger.

The experiment he proposes to be varied with a larger glass placed farther from the table, and to make use of bits of leaf gold instead of papers, esteeming that this will succeed much better, so as perhaps to make the gold rise and fall in spiral lines or whirl for a time in the air, without touching the table or glass.

Ordered that this experiment be tried the next meeting."

A.—An apparatus with flint glass as used by Newton. Its action is uncertain, depending on the hygroscopic condition of the glass. It may fail, as it did when first tried at the Royal Society. Application had to be made to Newton for further directions. In dry weather and with vigorous rubbing it works admirably.

B.—An apparatus with silica glass. This can be taken out and warmed over a spirit lamp; it will then work without fail.

C.—An apparatus with a sheet of celluloid replacing the glass. This will work at any time without fail, if lightly stroked with the dry hand.

NEWTON AND THE SCIENCE OF TO-DAY

By SIR JAMES JEANS, O.M., F.R.S.

THREE hundred years have elapsed since Newton was born, and 276 since his fertile mind had conceived most of those fundamental ideas, the development of which was to add such lustre to his name and be of such outstanding value to science: in astronomy the idea of universal gravitation; in physics the theory of colours; in mathematics the differential and integral calculus (or, as he would have said, the direct and inverse fluxions) as well as the binomial theorem and the method of infinite series. He tells us he had thought of all these before he was twenty-four years old, although he wrote little about most of them until many years later.

The intervening years have seen Newton's ideas examined, tested and developed as no other set of scientific ideas ever has been, and it might seem that by now we ought to be able to assess his greatness and place him in his rightful position relative not only to the science of to-day, but also to that of all time.

We have no doubts as to his greatness, but we probably feel less confidence in our powers to assess his ultimate position in science than we should have done fifty years ago, and certainly less than his immediate successors felt. For they were not content merely to claim outstanding greatness for Newton; they went on to claim a quality of finality and uniqueness which we know better than claim for him to-day.

Laplace, for example, wrote that the "Principia" was assured *for all time* of a pre-eminence above all other productions of the human intellect, while Lagrange, after expressing himself in similar terms, went on to say that Newton was "not only the greatest genius that had ever existed, but was also the most fortunate, for, as there is only one universe, it can fall to only one man in the world's history to interpret its laws".

Such eulogies as these are in striking contrast with Newton's own modest estimate of himself. As his life was drawing to its close, he made the much quoted remark that to himself he seemed only like a boy playing on the sea-shore, "and diverting myself," he said, "in now and then finding a smoother pebble or a prettier shell than ordinary, while the great ocean of truth lay all undiscovered before me".

Which of these two estimates, we may ask, is the nearer to the truth? And how far is it possible to reconcile them? Newton's contemporaries obviously could not have reconciled them. Can we?

All work in mathematics, no matter how modest it may be, may claim immortality if only it is accurate, since absolute truth can have nothing to fear from the disintegrating influence of time. But it is different with work in astronomy or physics. This must at best be relative to the knowledge, or even to the hypotheses, of its time, so that an increase of knowledge or an abandonment of hypotheses may at any time show it to be of no permanent value. This is as true of the work of Newton as of that of lesser men.

Yet Newton's contemporaries, as well as many generations after them, made the mistake of supposing that Newton's work in astronomy and physics possessed the same sort of absolute validity as his discoveries in mathematics; they thought that no future scientist would ever be able to penetrate to the innermost recesses of Nature's temple and discover more of her fundamental mysteries, because Newton had been there already and had seen all that there was to see. But we of to-day know that Nature's temple has many chambers, room after room, and that Newton had scarcely penetrated farther than the ante-chamber. Our thoughts turn to the work of Planck, Rutherford and Einstein. The ante-chamber which Newton had explored was familiar ground to them, but they found the keys to other, and hitherto unsuspected, rooms; in these they discovered laws every bit as fundamental as any that Newton discovered. We see that Newton was wiser than his contemporaries in his vision of the great ocean of truth which lay all undiscovered before him. But does this add to his intellectual stature or diminish it? Should it make him seem greater or less in our eyes?

There are some—although mostly laymen in science—who see science primarily as something that is for ever changing. For them the science of any period is like the sand-castles that the children build on the sea-shore; the rising tide will soon wash them away, and leave the sands clear for the new array of castles which will be built the next day. Those who hold such views are led, somewhat naturally, to make such statements as that Newton is out of date and superseded.

But the comparison is obviously faulty. Science is knowledge, and the primary characteristic of knowledge is not that it is for ever changing, but that it is for ever growing. Of course, all growth implies change, so that science must continually change—like the tree which is for ever budding out in new directions—but this is only a secondary effect. The correct comparison is not with sand-castles, which change because they are continually washed away and replaced, but with a vast building which changes as one floor is built on top of another, or a new wing is built where none stood before. This building is not like a medieval cathedral, the creation of a great number of artificers, each building after his own taste and fancy. It is an embodiment of scientific truth, and the truths of science are the same, no matter who discovers them. Whatever artificers build the structure, the blue-prints have previously been drawn by Nature herself, so that, had Newton lived or not, the building must at some time or other have looked pretty much as it looks to-day. And if we are to estimate how much modern science owes to Newton, we must not only consider how much Newton built himself, but also by how much he expedited the building—to what extent, to put it crudely, did Newton act as a catalyst to the growth and consolidation of scientific knowledge?

Let us first consider the significance of Newton's work in pure mathematics. There have been instances in this subject—especially in the theory of numbers—where a worker has stated a theorem which he believed to be true, but which centuries of discussion have not succeeded in either proving or disproving. Newton's mathematical work was not of that type. His *métier* was not the discovery of fanciful but comparatively useless theorems in recondite branches of pure mathematics, but the forging of practical tools which were urgently needed for further scientific progress, and we may be sure that if Newton had not forged them someone else would have done so in time.

For example, Newton hit upon the binomial theorem in two distinct ways. He, of course, knew the expansions of $(1 - x)$ raised to integral powers—squares, cubes, etc.; these are easily found by simple multiplication. Starting from these known expansions, Newton interpolated to find the values of the coefficients when $1 - x$ was raised to intermediate values, such as $\frac{1}{2}$, $\frac{3}{2}$, $\frac{5}{2}$. . . . He also calculated the value of $(1 - x)^{1/2}$ by taking the square root of $(1 - x)$ by the simple rules of schoolboy arithmetic, and of course found that the result confirmed what he had already obtained. It is hard to imagine that such simple artifices could have remained untried for long; the binomial theorem was simply a nugget lying on the direct road of progress, and it is quite inconceivable that generations of mathematicians could have passed it by without noticing it.

It was much the same with the greater discovery of the method of fluxions. Rouse Ball tells us that, before Newton appeared on the scene at all, the method had been foreshadowed in the writings of no fewer than seven mathematicians—Napier, Kepler, Cavalieri, Pascal, Fermat, Wallis and Barrow. In the more convenient and practical form of the differential calculus, it was actually discovered by Leibniz in 1675, and published to the world in 1684—nine years before Newton published his fluxional calculus. Apart from the personal questions involved, the bitter controversy as to whether the two discoveries were entirely independent, or whether Leibniz got ideas from seeing Newton's earlier letters on the subject, seems to me relatively unimportant; the calculus was simply another nugget lying on the direct line of scientific advance, and someone was bound to notice it and pick it up—if not to-day, then to-morrow; if not Newton, then Leibniz.

When we turn to consider Newton's still more famous work in mechanics and astronomy, we find the same story repeated; he did not drag science after him into peculiar paths of his own choosing, but kept to the broad main road, discussing the same problems as others were already discussing. The fundamental ideas with which he worked were not in any way novel, or peculiar to himself. His first law of motion had been given by Descartes in 1644, and indeed Plutarch had given it fifteen hundred years earlier together with a foreshadowing of the general principles of planetary motions, and the conception of gravity extending as far as the orbit of the moon. In his "De facie in orbe lunae", Plutarch had written, "You fear that the moon may fall, on the grounds that only light air circulates under the moon and that this is not adequate to bear a solid weight. But the moon is secured against falling by her motion and the swing of her revolution—just as objects put in slings are prevented from falling by the circular whirl. For everything is carried along by the motion natural to it, if it is not deflected by anything else."

Much the same, again, may be said about Newton's famous law of gravitation. The attraction of lodestone for iron had familiarized men with the idea that matter could attract other matter across empty space and, so far back as 1600, Gilbert in his "de Magnete" had conjectured that the earth might attract the moon like a magnet. Kepler had gone further in the same direction in 1619; we fi insisting on the mutual attraction of all matt instancing the tendency of all objects to fall towards the centre of the earth, as well as the ocean tides which, he maintained, were caused by the attraction of the moon. He said that two stones out in free space would approach one another, like mutually attracting magnets, and would finally meet at the point which we now call the centre of gravity of the two. He thought that the planets were kept moving in their orbits by some power inherent in the sun, and, although forming a very wrong idea of the nature of this power, he conjectured that it must vary as the inverse square of the distance. However, he immediately abandoned this law in favour of one varying inversely as the simple distance, a change which was challenged by Bouillard, who insisted that the true law must be that of the inverse square. Indeed, one of Kepler's own laws—that connecting the periodic times of the planets with their distance from the sun—shows clearly that the true law cannot be other than the inverse square law. Newton tells us that he had already noticed this in the plague years 1665 and 1666, but he did not publish it until it had been noticed independently by Hooke, Halley, Huygens and Wren.

Looking back on all this, we can scarcely accept Wordsworth's description of Newton's mind as

> "for ever voyaging through strange seas of
> thought alone."

Except in optics, where he voyaged alone because everyone else had lost the way, Newton's ideas were very much those of his contemporaries. His main achievement was not, as is so often stated, that he was the first to think of gravity as extending to the orbit of the moon, for this had been thought of fifteen hundred years before he was born. Neither was it that he was the first to think of universal gravitation, for many had thought of it before him. Neither was it that he was the first to conjecture that the force of gravitation must fall off as the inverse square of the distance, for this idea was generally current in his time. It was not even that he was the first to understand the general principle of planetary motions, for others understood these equally well.

Newton's great service to science, and through science to the human race, was not that he for ever voyaged through strange seas of thought alone, but that he voyaged through familiar seas of thought—if not in company with others, at least in seas that were much frequented by others. Bacon had written of his own contributions to scientific thought, that they did not originate in any mental powers of his own, but rather in the spirit of his age—"partus temporis potius quam ingenii". It was this same spirit of the age that moulded the form of most of Newton's contributions to science. Scattered scientific ideas—and unproved conjectures in particular—were floating around in abundance, and lesser lights of the firmament had made small, hesitating and uncertain advances in many directions. The age was crying for a man who could systematize, synthesize and extend the whole, and it found him in superlative excellence in Newton. But beyond all this, mental powers such as Bacon had disclaimed for himself were present in overflowing measure in Newton—"qui genus humanum ingenio superavit".

His special talents, as I see them, were: first that, out of a large mass of confused ideas provided largely by others, he was able, with his clear and acute mind, unerringly to pick out the true and discard the false; second that, having done this, his amazing mathematical ability enabled him to replace conjecture by proof, and so provide a firm basis from which he could unhesitatingly advance; third that he did advance, with quite incredible speed, sureness and directness, his supreme mathematical ability enabling him to outstrip all competitors with the utmost ease. From *conjecturing* that a thing is so to *knowing* that it is so, is usually a very long journey; it is one which Newton was so often able to take when his competitors were not. For example, Kepler had *conjectured* that the law of gravitational force might be the law of the inverse square; Newton *knew* that it could not be anything else. Kepler was so far from certain knowledge that he immediately abandoned this conjecture for another; Newton could not be misled into so doing, because his mathematical investigations provided him with convincing proof of the truth of his ideas. Having once settled his fundamental ideas and feeling full confidence in them, he was able to stride forward into the unknown with sure and rapid steps until he had unravelled almost the whole mystery of the then known universe.

In general it was not in originating ideas but in developing them that Newton's greatness showed itself most outstandingly; he was primarily a synthesist and systematizer. Yet here, as ever when we try to compress his genius into a formula or to map out its boundaries, an exception turns up to suggest that it overflowed all limitations; here it is the optics.

If we wish to understand the fundamental cause of his success, we cannot do better than read what Macaulay wrote in his "History": "In Isaac Newton two kinds of intellectual power which have little in common, and which are not often found together in a high degree of vigour, but which are nevertheless equally necessary in the most sublime departments of physics, were united as they have never been united before or since. In no other mind have the demonstrative faculty and the inductive faculty coexisted in such supreme excellence and perfect harmony." Einstein delivers a similar judgment even more forcibly: "In one person he combined the experimenter, the theorist, the mechanic and, not least, the artist in exposition. He stands before us, strong, certain and alone: his joy in creation and his minute precision are evident in every word and in every figure." And in truth he was unmatched both in the breadth and depth of his powers. Both contributed to his success. But if anything, the breadth was more in requisition, and so made the greater contribution to the success.

Yet if we are to estimate the extent to which Newton, with his outstanding mental power and unique combination of talents, expedited the growth of scientific knowledge, we cannot but place to the other side of the account his unfortunate habit of keeping his results to himself until they had been discovered independently by someone else. To some extent, this also may be ascribed to the spirit of the age. The seventeenth century had but little of our vision of science as a great benefactor to the human race, or of new knowledge as something which ought to be disclosed at once so as to expedite further progress by others. A man's scientific discoveries were his private property, with which he could do as he liked. Often his ambition was not to enable others to benefit from them, but to prevent others benefiting from them—this is why he would often publish his results in cypher. Or he might regard science, and mathematics in particular, as a sort of mental gymnasium in which contests of skill took place, and competitors issued challenges to one another to determine which of the two was the stronger or quicker. To use Newton's own metaphor, science was, more than to-day, a matter of playing with pebbles on the seashore, and seeing who could find the smoothest pebble or the prettiest shell. Thus there was less feeling of moral responsibility than now, perhaps even less interest in science for its own sake.

So we see Newton's terrifically powerful mind playing with the problems of science like a cat which plays with a mouse and loses all interest when he has killed it, or as we play with a crossword puzzle and regard the incident as finished when we have solved it.

We can see this exemplified in nearly all Newton's major discoveries. He tells us that he had thought of the method of fluxions in the plague year of 1665. Yet before publishing it even partially (except in cypher) to the world, he allowed twenty-eight years to elapse—years in which Leibniz discovered and published the same thing—and it was not fully published until 1736. Again in this same year of 1665, Newton satisfied himself that a force of gravity obeying an inverse square law explained the motion of the moon "pretty nearly", and was content to leave it at that. Later, he found that this same law would result in the planets describing the exact orbits they were known actually to describe—ellipses with the sun in one focus. Again he was content to leave it there. Most men would have published this as proof positive of the law of the inverse square, but Newton kept it to himself until Halley travelled to Cambridge to consult him on this very problem. Newton then explained that he had solved the problem five years previously, but had mislaid his proof. Finally, Prof. Andrade has reminded us of the reluctance with which Newton published his "Principia"—probably the greatest single work of the human intellect—and of the pressure which had to be applied before he would do so.

Apart from the general secretiveness of his age, we may perhaps find three further causes for this delaying tendency in Newton: an over-active mind which refused to halt by the wayside to perfect and write out results, a disinclination to be satisfied with anything short of perfection, and an extreme sensitiveness to criticism and consequent desire to avoid controversy, this resulting more than once in a disinclination to pursue the study of science any further. In spite of these handicaps Newton bestrode the scientific world like a Colossus: what would he have been without them?

Such was the man as I see him; let us now consider how much of the scientific edifice which Newton built, or was built under his influence, is still in useful service to-day.

Outside pure mathematics, Newton's procedure was simply that of every other true man of science. He started from known facts which, in his judgment, seemed likely to be related—as for example, if legend can be trusted, that apples fall to the ground with an acceleration of 981 C.G.S. units, and that the moon circles round the earth once every 27⅓ days—and tried to represent the isolated facts of such a group as special instances of a general system of laws. If this could be done, the set of laws so discovered could be made to predict other phenomena, which could then be submitted to the test of experiment or observation. If the laws passed this test, they were assumed to correspond to something in ultimate reality; provisionally at least they were true laws, and showed how Nature worked. If Newton differed from others, it was in the greater range of facts on which he worked.

In any scientific era, the search for such sets of laws is clearly restricted by the range of facts which are known, or are capable of being known, at the time; and we cannot expect scientific men to discover laws of a higher order of accuracy than the observations through which the laws are discovered.

Some may challenge this, arguing that a genius of sufficient stature ought to be able to discover the true reality behind Nature from quite meagre evidence—"ex pede Herculem"—and that, when this reality was known, the laws governing its behaviour could be deduced and would necessarily be true throughout the whole range of phenomena, whether known or still to be discovered. Unhappily, Nature is not like that. Science can, from the nature of things, never attain to a knowledge of the realities of the world, but only to a knowledge of the phenomena—of the impressions that the world makes on our senses, generally, of course, through instruments of precision. Our sense-organs form a sort of screen on which Nature's lantern is for ever projecting pictures; we can study these pictures, but can never pass behind the screen to see how the lantern works. As the sequence of pictures thrown on the screen is all that we can ever know or study, a set of laws that links the pictures together in a perfect systematic order is the most that science can provide, or can properly be asked to provide. If meagreness of the instrumental equipment in any age prevents the science of that age from knowing the finer details of the pictures, then we cannot expect the science of the age to provide laws governing these fine details.

For this reason we have to introduce a sort of relativity into our conception of the aims of physics; we may say that the science of any age can aim no higher than at predicting the result of any experiment that can be performed *in the age in question*. If this is conceded, we may claim that by far the greater part of Newton's work was accurate and final, relative to the age in which he lived; and this part is still of value and still in use to-day.

The enormous increase in instrumental power which has occurred since Newton's time has thrown open new fields for exploration in two directions—towards the infinitely great and towards the infinitely small, from the electron at one end of the scale to the nebulæ and the whole of space at the other. Man and the man-sized world with which Newton was mainly concerned lie about midway between these two extremes.

The laws of Nature are of course universal, so that the same set of laws must prevail throughout the whole of this range, but different aspects of these laws assume importance in turn in different parts of the range. So much is this the case that we may almost regard the different parts of the range as constituting separate and detached worlds in which completely different sets of laws prevail. There is the small-scale world of electrons and of atomic physics in general in which the laws of quantum mechanics prevail, the man-sized world in which the laws of molar mechanics prevail, and the world of the great nebulæ in which the laws of relativity prevail. These three worlds are all governed by the same laws, but factors which are all-important in one become mere insignificant corrections in the others. Newton's work was applicable almost exclusively to the middle-sized world of molar mechanics, and so not in general to the other two worlds, the existence of which was scarcely suspected in his day. Lagrange was wrong in thinking that there was only one universe, and that it could fall to only one man to interpret its laws; there are worlds within worlds, and Newton had only interpreted the laws of one of these. Relative to this world most of Newton's work was accurate and final, which means that it was also accurate and final relative to the age in which he lived.

If we examine any recent paper on theoretical physics, we are likely to find it plentifully sprinkled with either the symbol h or the symbol c, or both. These two symbols were unknown to Newton, at least in the sense in which we now use them; they are, so to say, the emblems of the theories of quanta and relativity which did not invade physics until the present century.

The symbol c denotes the velocity of light, which is greater than the velocity of any material object, and is usually enormously greater. Also in dynamical problems the ratio of these two velocities can only enter through its square. We are now familiar with electrons which move almost as fast as light, but the kind of dynamics with which Newton was concerned contemplated no velocity greater than that of the planet Mercury, which is about 48 km. a second. For this, the ratio of the squares of the two velocities is 0·0000000256, or, to seven significant figures, is *nil*. If we disregard this fraction, the dynamics of relativity becomes absolutely identical with that of Newton, so that to seven significant figures Newton's dynamics was adequate and factually perfect for an age in which nothing moved faster than the planet Mercury.

It is the same with the h of the theory of quanta. This measures the atom of action which Planck discovered in 1899, and although it is of the utmost importance to phenomena on the atomic and subatomic scale, it is absurdly small in comparison with the amounts of action involved in the activities of everyday life. Roughly speaking, the ratio is that of an atom to a gram, or of a gram to a star. This small quantity again was quite negligible in all the problems with which Newton was concerned.

Thus the Newtonian mechanics, dynamics and astronomy were absolutely right factually, except for quantities which were so small that they could not either affect Newton's problems in any way, or make their existence known through the best instrumental accuracy that was available in his day. To see Newton's work in these subjects in their proper perspective, we must think of him as the builder of the ground floor of the great building of mechanics, dynamics and astronomy, and as its architect for many floors above this. Newton's first and last serious contribution was his "Principia", but after this, floor after floor was added on strictly Newtonian lines: on the dynamical side, the generalized dynamics of Lagrange, Hamilton and Jacobi; on the astronomical side, the dynamical astronomy of Laplace and many others; on the physical side, the electrodynamical theory which we associate primarily with Clerk Maxwell. All this and much more followed the Newtonian architectural plan without any deviation whatever for two centuries. It was not until 1887—just two hundred years after the appearance of the "Principia"—that the Michelson-Morley experiment first showed that the Newtonian scheme was in actual fact imperfect. But the experiment had to be discussed for eighteen years before this inference was drawn, and it was only when Einstein's restricted theory of relativity appeared that the Newtonian scheme was generally recognized to be inadequate.

It is, however, inadequate only with reference to the ultra-refinements of modern science. When the astronomer wishes to prepare his "Nautical Almanac", or to discuss the motions of the planets, he uses the Newtonian scheme almost exclusively. The engineer who is building a bridge or a ship or a locomotive does precisely what he would have done had Newton's scheme never been proved inadequate. The same is true of the electrical engineer, whether he is mending a telephone or designing a power-station. The science of everyday life is still wholly Newtonian; and it is impossible to estimate how much this science owes to Newton's clear and penetrating mind having set it on the right road, and this so firmly and convincingly that none who understood his methods could doubt their rightness. Without his guidance, smaller men might have argued for centuries as to what was right and what was wrong. When Newton had spoken, it soon came to be recognized that the time for controversy as to which was the right road was past; it only remained to advance along the Newtonian road.

Newton's work in optics stands somewhat apart from the rest, in that he was much less indebted to his predecessors and contemporaries. Indeed, current ideas on the nature of light were so vague and erroneous that he was probably hindered rather than helped by what he knew of them, and was perhaps fortunate in not knowing more. We know that he attended the lectures of Barrow in Cambridge, where he would doubtless become acquainted with the optical theories of Descartes as well as with those of Barrow himself. Now Descartes thought that all space was filled with substance, and that vision resulted from the transmission of a pressure from one particle to another of this substance—much as a blind man pokes about with a stick. He thought that different sensations of colour resulted from the particles rotating with different speeds, red resulting from the most rapid rotations, and yellow, green and blue following in this order. Barrow held even more fantastic opinions; he thought that red light was more concentrated than light of other colours, but was broken up by intervals of complete darkness, yellow light consisted of a mixture of this red light with white, and so on. Hooke conjectured that light consists of a rapid vibrational motion of an ethereal medium filling all space, different colours being produced by different shapes of wave; blue, for example, resulted from "an oblique and confused pulse of light".

Into the midst of all this confusion of thought came Newton, to whom, in Einstein's words, "Nature was an open book, whose letters he could read without effort. The conceptions which he used to reduce the material of experience to order seemed to flow spontaneously from experience itself, from the beautiful experiments which he arranged in order like playthings." With the prism he had bought at Stourbridge Fair, he went at once to the crucial experiment of the spectrum. Finding that this was longer than it was broad, he at once saw that differences of colour must result from different degrees of refrangibility. This discovery alone, the subject of Newton's first scientific paper, published in our *Phil. Trans.* of 1672, at once took the theory of light leagues beyond the point to which any previous investigator had brought it, and opened the road to further rapid progress.

But Newton brought his views into discredit in the eyes of many by appearing to think of light as a material substance—Hooke definitely brought this charge against him. Actually Newton repeatedly claimed that his results did not depend on any special views as to the ultimate nature of light, and he was careful to avoid such words as 'corpuscles' which might seem to imply such views. Yet much of his thought seems to become meaningless unless we identify his rays—the "least parts" of light—with something of a corpuscular nature. However little he may have said about it, Newton seems always to have had his own picture of the structure of light before his eyes, and this picture was corpuscular.

For two centuries many thought of this as the one serious mistake that Newton ever made. Recently the pendulum has swung—perhaps too far—in the other direction. Light is a transfer of energy from matter at one place to matter at another, and this transfer can only take place by complete units, or 'quanta'. This led Einstein to picture light as a shower of arrows, each arrow containing a single complete quantum of energy, and some have hailed Newton's corpuscular theory of light as a brilliant prevision of this.

But we must remember that Newton introduced his corpuscles primarily to explain the rectilinear propagation of light, whereas Einstein introduced his light-arrows to picture the quite different property of atomicity. This being so, the similarity of the two pictures can scarcely be quoted as a supreme example of intuition on the part of Newton. It might be if light really did consist of corpuscles; Newton would then have arrived at the truth by one road two hundred years before Einstein reached it by another. But no competent physicist can for a moment suppose that light consists either of corpuscles or of light-arrows; these are only pictures we draw for ourselves to help us understand parts of a truth which we know, as a whole, to be for ever beyond our comprehension.

At this point we are inevitably brought to consider Newton as a philosopher. Unlike his great predecessor Descartes and his great contemporary Leibniz, he seems to have had very little interest in philosophy for its own sake. He was what we might describe to-day as a pragmatist; his main concern with a philosophy was not as to whether it was true, but whether it worked and yielded useful results. It was another illustration of the ever-recurring difference between the British and the Continentals.

Descartes had taught mathematicians to measure co-ordinates from fixed lines on a piece of paper. Newton wanted to be able to measure mechanical and astronomical co-ordinates in the same way from positions in space and instants in time. So he assumed without further ado that time could be measured from a fixed standard instant, and that the remotest parts of the universe contained vast immovable masses, providing standard positions against which absolute motion could be measured.

This assumption of the existence of absolute time and space was a mere working hypothesis which, as he admitted, might not be true at all: "it may be that there is no body really at rest, to which the places and motions of other bodies can be referred". But the assumption, whether true or false, produced results—nothing less than a consistent scheme which explained a large part of the then known workings of Nature. This being so, philosophers such as Bruno and Leibniz might argue in vain that absolute space, time and motion were meaningless and illogical.

It was much the same in mechanics. In the man-sized world of seventeenth-century science, motion was the result of pushes or pulls of the kind that a horse exerts on a cart. Other suggested causes of motion, such as action at a distance, were regarded much as we of to-day regard levitation or table-turning, and described as "occult qualities". It was inevitable that Newton's force of gravity should come under this description. Leibniz wrote, "Some men begin to revive, under the specious name of forces, the occult qualities of scholasticism, but they bring us back again into the Kingdom of Darkness". Newton's reply was a fine defence of his pragmatical philosophy. To understand the motions of the planets under gravity, he says, even though we do not know the cause of gravity, is as good progress in philosophy as is a knowledge of the motions of the wheels of a clock in the philosophy of clockwork, even though we do not understand why the weight which moves the wheels falls earthward.

At the same time, he refused to admit that his gravitational forces were not wholly mechanical. From the celestial phenomena, he said, we calculate the force of gravity with which bodies are drawn to the sun and the several planets. Once having found these, we deduce the motions of the planets, the comets, the moon and the sun, and "I wish we could derive the rest of the phenomena of Nature by the same kind of reasoning from mechanical principles".

It is interesting to speculate as to what might have happened if Newton had shared the views of Leibniz as to the relativity of all motion. It is conceivable that he might have arrived speedily at what we now call the restricted theory of relativity, that through it he would have seen the impossibility of action at a distance, and would then have developed a relativity theory of gravitation similar to that of Einstein. It is conceivable, but I can scarcely think it would have happened—the necessary physical ideas and mathematical technique seem to be centuries removed from the fields in which Newton worked. It is more likely that he would have been compelled to come down to an approximation which would have brought him back to the Newtonian mechanics and the inverse square law. If so, his erroneous philosophical background of absolute space and time was a real advantage, since it provided him with a short cut to a region which would have had to be explored anyhow as a preliminary to further progress. It enabled him to go direct to the main point as it appeared in the seventeenth century, neither hindered by any philosophical subtleties nor haunted by any fears that his system might not be an expression of final absolute truth.

In this way Newton created a system which, although philosophically unsound, was destined to endure for two centuries before any chinks were found in its armour. Then more philosophically minded Continentals had to be called in to patch up the deficiencies.

In this quality of practical and opportunist directness, as in many others, Newton seems to me to be typically British. In general he excelled where the British excel, and was weakest where the British are weak. If we think of his various pre-eminences in turn, and consider who runs him closest in each, we shall find it is usually a British man of science who comes to mind. If we try to match the simple directness and the clear logical sequence of his experiments in optics, our thoughts turn to our own Faraday and Rutherford. Clerk Maxwell runs second to him, I think, in other aspects of his work. But if we think of those who excelled him in his philosophical outlook, we have to think exclusively of Continentals, from Leibniz on. His successes were typically British, and his failures—in so far as he ever failed—were also typically British. We can not only be proud that this greatest of all scientific men was our own countryman, but we may reflect with satisfaction that he was no freak genius or sport, but was the concentrated embodiment of all the distinguishing characteristics of British science.

FUTURE OF UNIVERSITY EDUCATION

THOUGH the report (outlined on page 718 of this issue) of the Committee appointed by the British Association to consider university education after the War is only of an interim nature, it contains so much of outstanding and immediate value (if any of its proposals are eventually to be put into effect) that it warrants the close attention of all those interested in formal education and those who appreciate the valuable contributions which education will be able to make towards the new world order.

The Committee is obviously determined to pursue its policy of eliminating the defective and strengthening the weak spots in university education, of modifying certain systems and traditions, and of seeing that those universities which have suffered through the evil effects of actual warfare, or the even worse results of occupation by an unscrupulous enemy, are rehabilitated after the War. It is plainly anxious that all this shall be carried out in such a manner as to bring the maximum benefit not only to the universities immediately concerned but also to the whole international community. We tend at times to look upon university training as a means to an end which affects university men and women only; this is not only a very narrow but also a dangerous point of view, for universities are national institutions just like parliaments, and exist not only for the benefit of those who gain admission to them but above all for the community in general. The best material must be voted into them, and they must continue to make the best of that material so that their final products shall be not only a credit to themselves but also a distinct asset to the whole community.

Having read this interim report, we are satisfied that the Committee is treading the right path. It also indicates certain angles of approach which it proposes to make later on, and these indications, stated or implied, suggest that there will be much more for us to consider seriously when the final report becomes available. For that reason, only certain sections of the present report are sufficiently advanced to warrant useful comment.

The proposal that the 'modal' age of entry into the university should be nineteen is (apart from wartime contingencies) timely and deserving of support. Some of those actively concerned with university education have often expressed concern over the immature type of undergraduate gaining access to the universities. A first-year university student is in no way comparable to a sixth-form secondary school pupil, and the growing tendency to-day for a student to do his nominal first university year while still at school, and thus enter upon his second year when beginning his university career, makes the problem even more acute. When a student enters a university he finds himself thrown very much on his own resources, and often for the first time in his academic life has to make important decisions for himself in spite of university codes and regulations and tutorial supervision. Those university teachers who have had such students under their charge must often have noticed that many of them are too immature and indeed unready for such responsibilities.

Closely knit with the proposal to raise the age of entry, at any rate in its effect, is the Committee's proposal that a student should have given a year of national or international service or have had a year's education abroad before entering upon his university career, for thus will his mind be broadened and his sense of responsibility and of values be strengthened. Thus would students attain that greater appreciation of the value of social intercourse, greater maturity of mind and more experience of life, all of which have been so lacking for years past in our university freshmen. When they enter the university, they should be fit to take immediate advantage of the greater freedom from rules and regulations and of the fact that they are now treated as men and women and not as boys and girls. In present conditions too many fall victims to what is to them a new regime.

The comments of the Committee on entrance tests and scholarships will receive widespread support because such views have been expressed so often before, though, alas, little action has been taken. The present form of entrance examination is soul-destroying. The teacher in the school is tied not only by the examination system, but also by the peculiar requirements of that university which his pupils hope to enter. Though we would be the last to press for absolute standardization at the expense of individual development and expression, we strongly support the Committee's suggestion that there should be some form of standardization of examination so far as general education is concerned. Specific and special knowledge must, if necessary, be tested individually; but such a requirement should be imposed only in exceptional cases, otherwise the evil effects of examinations will always be with us. The time is also propitious for those universities which insist on a pass in certain definitely stated subjects in their entrance examinations to pause to consider whether such provisos (for that is what they really are) are necessary and, indeed, whether such rulings are not harmful. We have no quarrel with the demand for a reasonably high standard in English, mathematics, science, and other subjects of cultural value; but it is difficult to see the reason for making such subjects as Latin or Greek compulsory, as certain universities do. It is well known that in many such cases, candidates, who have never studied Latin before, read enough, after passing their School Certificate examination, in order to pass university entrance, and then begin forgetting all about it. Surely, with all due respect to a sincere study of the subject, this short-term cramming is an unnecessary waste of time and is quite meaningless.

The most potent effect of the Committee's proposals concerning this type of examination will be felt in both directions, that is, beforehand in the schools and afterwards in the universities. A better type of student would be the universities' share, whereas in the schools the pupils would profit by equality of opportunity and a more all-round training, especially from the social point of view.

It is recommended that all students should reside for at least one year in a university college or a hostel. It is also recommended that every student should be placed under tutorial supervision. These recommendations are complementary. But, though the Committee sets our minds at rest so far as expense is concerned, the difficulties will prove greater than one might on casual consideration think. Such difficulties as might arise will, of course, be least in the collegiate universities and in some of those modern universities, such as Reading and Manchester, which have developed splendidly comprehensive hostel or hall systems. The fraternity and dormitory systems extant in certain American universities would also lessen the difficulties. But a year's residence in a hostel would lose much, if not most, of its value if not lived fully and seriously. This would not be easy in many modern British universities situated in large towns which draw most of their students from their immediate surroundings. The hostel system in such cases would have to be subjected to very strict discipline if outside, especially home and town-life, distractions are not to exert a very adverse influence. Tutorial supervision is practised to a greater or less degree in most of our universities. In some, where it is scarcely anything but nominal, it needs tightening up. Much will depend upon the tutorial staff, who ought to be specially trained for the purpose, since they are more like teachers than lecturers. But the system itself would be greatly helped by some form of internal residence.

We can offer little but praise for the Committee's recommendations for re-planning teaching departments and curricula in accordance with modern conceptions of the interrelation of different branches of knowledge. In fact they have been borne out so recently as December 2 by the Archbishop of Canterbury, in a speech delivered in London, in which he said we should take note of the balance between human and scientific subjects. Dr. Temple considers that the pendulum has swung too far in the direction of scientific training. We tend to produce people whose conscious thinking is almost entirely governed by the methods of the laboratory, and whose minds only move freely when they are dealing with what can be measured, weighed and stated with exact precision. As Dr. Temple claims, this is not true of any human problem.

This carries our minds back to an address made by the same speaker about twelve years ago in Manchester, when he pleaded for more research in the universities. This side of academic life has certainly developed, and there may lie the cause of the problem. Too much of the training of university students is left to research specialists. Research specialists are bound to give prominence to their own pet interests, and thus are often unable to strike a balance for the average student. It is clear that both the narrow specialist and the broad general teacher are required in the university of the future, for very often the best teacher in the university is only a second-rate research worker, and vice versa.

It is therefore with a feeling of deep satisfaction that we note the Committee's insistence on training for world citizenship in all faculties, pass and honours, of our universities. No university is justified in granting a first-class degree to a student who has simply passed satisfactorily through its faculty of science. Social studies and the humanities must play a certain part in the training of all students. This applies especially to science students, for it is almost axiomatic that, in present circumstances, a man might gain a first-class degree in science and be no more appreciative of the essentials of world citizenship than any less fortunate individual who has not gone so far as through a secondary school.

One misleading remark in the Committee's report is that its recommendations for the institution of honours and pass schools of "Philosophy, Natural and Social" would meet the "charges of neglecting the non-vocational education of citizens". It may be true that the ideal university education should not be influenced by vocational demands, but the fact still remains that nearly every university student treats his university career as a basis or qualification for a profession usually chosen beforehand. It is also true that those university departments whose subjects offer little or no vocational value often find themselves practically void of students. In this claim, the Committee seems to be too modest, for surely such a school of "Philosophy, Natural and Social" should prove to be the very best one for the future school teacher. In their examination syllabuses, the universities themselves are in large measure responsible for the narrow and far too specialized training given in our sixth forms; but another reason may be found in the type of honours man usually chosen for teaching such boys and girls. Give him, not an honours degree in one subject, but what the newly proposed course can offer, and then our university candidates from the schools would receive a wider training in sociology and citizenship than they do at present.

The Committee's attempt to link up natural and social philosophy in the history of discovery is deserving of very careful consideration. In our studies of discovery we are recommended to include "natural science or scholarship, studied in relation to social and political history". This should help university, and even school, teachers to break away from the belief that they are doing enough when they bring into their science courses the study of the works of such paragons as Newton, Faraday, Boyle, Darwin and Harvey. In this connexion, teachers are recommended to read Dr. H. A. Mess's "Social Structure", where a considerable amount of background is offered for such courses as are proposed by the Committee. For example, the period between 800 and 400 B.C. was notable for its advances in ethical thought. There we find such names as Lao-Tze, Gautama Buddha, and the Jewish prophets from Amos to the second Isaiah. In Greece during the fifth and fourth centuries before Christ, considerable additions were made to knowledge, especially in mathematics, physics, medicine and biology. Socrates developed the method of argument, and Aristotle was the founder of formal logic. Rome followed during 100 B.C.–A.D. 400 with contributions to engineering, government and the formulation of law. And so one could go on. This is the history of discovery—not the discovery of natural laws alone, but also of human relations.

It is certain that our science students need a much broader and deeper background to their training. They need to be given training not only in scientific method but also in the interrelation of science with the other cultural disciplines. By giving them this we make them think of themselves not only as wheels in a machine concerned only with their own movements, but also as necessary parts of that machine, the working of which they seek to understand—the machine of human culture.

All this, the British Association Committee clearly bears in mind in its deliberations, and for this it is to be congratulated on a very valuable piece of work, which, nevertheless, is only partially completed. The Committee has, much to its credit, kept in mind the most important needs in our universities of the future, namely, equality of opportunity, freedom of development, thought and speech, the promotion of international collaboration, needs and service of the community—or in one phrase, training for world citizenship.

BRITISH ASSOCIATION REPORT

ONE of the important questions raised at the Conference on Science and World Order, which was held in London during September 1941, under the auspices of the British Association Division for the Social and International Relations of Science[1], was that of post-war university education and the rehabilitation of universities destroyed or damaged during the War. A Committee was consequently formed to examine and report on the problems involved. This Committee, under the chairmanship of Dr. J. C. Maxwell Garnett, is composed of twenty-four members (several representing universities outside the British Empire), together with the president and general officers of the British Association, and Prof. F. E. Weiss and Mr. A. Gray Jones as joint honorary secretaries. The Committee presented an interim report to the Council of the British Association in September 1942, and this has now been published[2].

Entrance to Universities

The Committee recognizes that those who enter upon a university career should do so with a greater maturity of mind and a wider experience of life than has hitherto been the case. The 'modal' age of entry into the universities should therefore be not less than nineteen. During their nineteenth year, students should carry out some approved form of national or international service (civil or military). Where possible, this work should be related to the intended profession of the students of applied science. For example, engineers should do a year of workshop training, and medical students might either enter a hospital or do some other form of welfare work. In other cases, a year abroad could be accepted as one form of international service.

Entrance examinations should consist of two parts: (1) a test of general education; (2) a test of special knowledge. So far as (1) is concerned, an ever-widening group of universities (beginning with all those in the United Kingdom) should adopt each other's tests. This would not apply to (2), but each department of each university should satisfy itself concerning a candidate's special knowledge. Though this recommendation would not be seriously impaired if certain universities still insisted upon every candidate for matriculation possessing, as part of a general education, some one particular kind of knowledge (for example, Greek or Latin) not required by other universities in the group, the Committee expresses the view that the adoption of its recommendations should be subject to no such exception.

Personal character (purposefulness, enterprise, initiative and originality) should receive careful consideration, together with the generally examined knowledge and intellectual qualities of a candidate when he is being considered for a university entrance scholarship. One of the greatest advantages of this, so far as each individual is concerned, would be to increase equality of opportunity. The schools themselves would also benefit in that they would thus be encouraged to provide more all-round training, especially social, by means of out-of-school activities.

For every internal student, at least one year's residence in college or hostel should be enforced. The Committee states that this would not involve a prohibitive cost; but further inquiries are being made. Personal direction and watching of every undergraduate's studies should be more fully developed by the adoption or extension of the tutorial system.

Freedom for discussion should be the keynote of all university education. Freedom of thought and expression, especially so far as world affairs are concerned, should be assured.

An International Auxiliary Language

International communication will be indispensable after the War, and the universities can contribute towards this by requiring all their students to be able to make themselves understood, by speech and writing, in some one auxiliary means of international communication. This is not a question of learning another language but of devoting one long vacation to the acquisition of an auxiliary means of communication. Basic English, for example, has only 850 words, whereas the English language contains 240,000, while French has 100,000 and Italian 80,000 words. A sufficient acquaintance with Basic English could be obtained within a few days by the many post-war students who will be able to talk some English. Professional diplomats can, of course, transact their business in a common language. Since it ceased to be Latin it has generally been French and is likely, in future, to be English. English is one of the two languages of the Anglo-Soviet Treaty and the common language of Generalissimo Chiang Kai-shek and the peoples of India.

The desirability of promoting the introduction of an auxiliary language as an international means of communication was given particular attention after the War of 1914–18, and the position and prospects of this subject were surveyed in a report of a British Association Committee published in 1921. In order to present the problem in a comprehensive manner, the Committee communicated with leading authorities and associations having special knowledge of classical and modern languages as well as interest in the use of an international auxiliary language. The particular claims of three types of such a language were stated, namely: (1) A dead language, for example, Latin; (2) a national language, for example, English; (3) an invented or artificial language, for example, Esperanto and Ido.

The advantages and disadvantages of each of these types were considered by the Committee, which reached the following conclusions: (1) Latin is too difficult to serve as an international auxiliary language; (2) the adoption of any modern national language would confer undue advantages and excite jealousy; (3) therefore an invented language is best. Esperanto and Ido are suitable, but the 1921 Committee was not prepared to decide between them.

However, since the publication of the British Association's report twenty-one years ago, the great political changes which have taken place, or which will have taken place at the end of the War, point to the fact that any auxiliary means of communication will have to be closely related to the English language. The Universities Bureau of the British Empire, and the new Association of University Professors and Lecturers of Allied Countries in Great Britain[3], might well assist in promoting the movement for an auxiliary means of international communication by preparing a report on the question whether Basic English is suitable for the purpose, or, if not, what alternative is to be preferred.

International Education Organization

Experience in university and other kinds of education gained by the different countries of the world should be pooled by the formation of an international education organization representative of teachers (including university teachers), governing bodies, local education authorities and governments. The wider utilization of graduate scholarships, sufficient to cover passage money and all necessary expenses, should aid the exchange of students between the universities of different countries.

The universities should also associate themselves more closely with non-vocational adult education.

Replanning University Curricula

Another term of reference of the British Association Committee is "To consider the replanning of teaching departments and curricula in accordance with modern conceptions of the interrelations of different branches of knowledge, particularly those of science and the humanities".

University studies are still showing a tendency to split up into a growing number of separate specialisms, very remarkable for their diversity. These tend to become increasingly removed from the life of the community. The Committee has therefore considered two proposals: *A*, a general degree course including both natural sciences and the humanities; *B*, a proposal to include courses of the elements of sociology and citizenship in the already existing specialized schools of natural and applied sciences.

The recommendations concerning *A* are partly derived from the proposals for an Honour School of Philosophy and Natural Science which were considered in 1923 by the University of Oxford and which have recently been informally revived. The crux of the recommendation is the institution of honours and pass schools of "Philosophy, Natural and Social". Here the modern world would be studied as an integrated whole against a background of modern science. The course of study would include the natural and the social sciences with the ultimate aim of constructing (as expressed in Whitehead's "Process and Reality") "a system of ideas which bring the æsthetic, moral and religious interests into relation with those concepts of the world which have their origin in natural science".

In such a course, chemistry and physics would come together under 'physical science', and zoology, botany and physiology under 'biological sciences'. During the study of these subjects, detailed knowledge would be looked upon as being less important than an apprehension of scientific method. Observational and experimental work would, however, have to be included. Along with these courses, there should be courses in the history of discovery, not only of inventions but also of ideas and conceptions. The study of man and society, including the contemporary international community, should be begun in the first year and extend through the next. The last year would then link together all previous work, whether in natural sciences or the humanities, and bring it in relation with the best philosophic thought of the Western world, begun by Plato and Aristotle and continued by the greatest modern thinkers from Descartes to Whitehead.

The Committee gives a warning against having separate tutors directing study of the separate subjects; the whole course must, to be effective, be treated as an integrated whole—an organized unity.

Proposal *A* is designed by the Committee to provide for the "non-vocational education of citizens". Proposal *B* should ensure that the importance of the interrelation of science and the humanities be also recognized in the specialized courses for students preparing for a professional vocation of science. For reasons stated by the Committee (and reiterated time and time again in NATURE and elsewhere), all students in the faculties of science should attend some discussion classes in subjects outside their specialism. Here such students should be addressed by persons who understand their background interest; the students are not recommended to attend courses of lectures in the faculties of arts and commerce.

There should be "special interest" courses; for example, medical students should attend courses on the public health services, vital statistics and human needs. These "special interest" courses should be followed by courses made up of discussion groups of a more general nature on citizenship, social and industrial relations, anthropology, psychology, and other branches of the humanities.

Such courses should cover the student's first two years, and should be enough to enable him to start thinking about social affairs, so that later on in his university career he will take complete advantage of the debating and political societies organized by the students themselves in their unions and guilds.

While claiming that all this is going in the right direction, the Committee warns against forcing the pace. The new teachers with the new outlook must eventually be created. This can be done, (*a*) by teaching general science in all schools, and (*b*) by providing courses in borderline subjects in the universities, such subjects to include social medicine and vital statistics in the faculties of science and medicine, social technology, demography and standards of human needs in the faculties of arts and commerce.

Rehabilitation of War-Damaged Universities

The British Association Committee has under survey the position regarding teaching material, apparatus, books and staff in universities which have been destroyed, damaged, disorganized or closed as a result of the War.

The Committee recommends that the United Nations should, at the time of armistice, require the enemy Powers to make full restoration of university property stolen or destroyed in the countries they have temporarily occupied.

Many scientific instruments and much apparatus now being put to war purposes would be of great value for teaching and research, and the Committee recommends that the Governments of the United Nations either give or lend them to the universities, especially those being rehabilitated after the War, and that they require similar action of the enemy Powers.

The Committee has obtained much information from the London International Assembly concerning war damage to the universities. Lists of up-to-date text-books as well as standard books and works of reference are being compiled. When these are sufficiently complete, they will be sent to British universities and university colleges and to the American University Union. It is then hoped to collect a large number of spare copies of such works. The Committee also recommends that the British Council consider buying certain books, and it is also hoped that publishers may supply, for the use of rehabilitated universities, books at reduced prices. It is also hoped to collect copies of learned journals or microfilms of them. The Committee may be able to arrange for the preparation of such microfilms.

It is the opinion of some members of the Committee, who are citizens of the Allied States in Europe, that it will be necessary for British and American universtities to train teachers and research workers for some of the universities whose staffs have been killed or dispersed by the enemy.

RECENT ADVANCES IN OUR KNOWLEDGE OF THE PHOTOGRAPHIC PROCESS*

By DR. C. E. KENNETH MEES, F.R.S.

Research Laboratory, Eastman Kodak Company

WHILE many materials are sensitive to light and can be used for making photographs, the present art of photography is based upon one specific process: the light-sensitive material is silver bromide in the form of extremely small crystals held in a layer of gelatin.

The direction in which advances have been made in recent years is in the elucidation of the structure of the light-sensitive materials and the factors which produce great sensitivity in the silver bromide crystals, so that very small amounts of light are sufficient to make them developable; in the study of the action of light itself and of the change which occurs in the exposed crystals; and in the study of the development reaction by which the exposed crystals are reduced to metallic silver.

The nature of the silver halide crystals and the origin of their sensitivity were elucidated between 1920 and 1930. An adequate theory of the nature of the reaction of light has only become available in the last three or four years, and our views as to the nature of the development reaction have changed very radically in the last year or two.

About twenty years ago, an attack was made on the origin of the sensitivity of the silver bromide crystals by three groups of investigators—Svedberg and his collaborators in Sweden, the British Photographic Research Association in England and the Kodak laboratories in Rochester, N.Y. Soon after gelatin emulsions were first made, it was found that the exposure required in the camera was greatly lessened if the emulsion had been cooked for some time at a high temperature or if it had been treated with ammonia. It was observed that the grains had grown larger during this treatment, and it was concluded that their greater sensitivity was due to their greater size. This is true, but it is by no means the whole story. For a long time, it had been known that if an emulsion were treated with some chemicals, such as chromic acid, it lost its sensitivity, even though the size of the grains was not changed. Also, sensitivity depends very much upon the particular kind of gelatin used in making the emulsion. No clue to an explanation was found until Dr. S. E. Sheppard studied systematically the various fractions obtained at each stage in the preparation of photographic gelatin.

Photographic gelatin is made from clippings from the skins of calves. For this purpose, the skin of the face and ears is used because these parts are of no value for leather. These clippings are first washed and then treated with lime for a long time to remove the fat and hair. The lime is removed by long washing with weak acid and then with water. Then the material is cooked in steam kettles until the gelatin is extracted, and the extract is concentrated if necessary and allowed to set to a jelly; the blocks of jelly are cut into thin slices and stretched out on nets to dry. Sheppard found that in the acid liquors in which the limed clippings had been washed there seemed to be a concentration of some sort of sensitizer, eventually identified as mustard oil, which contains sulphur.

When mustard oil is treated with alkali, it forms allyl thiocarbamide. If silver bromide is treated with a solution of allyl thiocarbamide, the surface of the silver bromide is attacked and grows a mass of white needles containing both allyl thiocarbamide and silver bromide. When these are treated with alkali, they break down into little black spots which must consist of silver sulphide because of the chemistry of the reaction.

When the development of grains is observed under the microscope, it starts from specks, these increasing in number and size until each grain is transformed into metallic silver. The question arises as to whether these centres of development existed before exposure or came into existence when development started. Sheppard's work put the whole matter beyond doubt. Sensitivity depends upon the existence of specks far too small to be seen in the microscope, and these specks consist of silver sulphide, probably derived from the mustard oil in the gelatin. The amount of

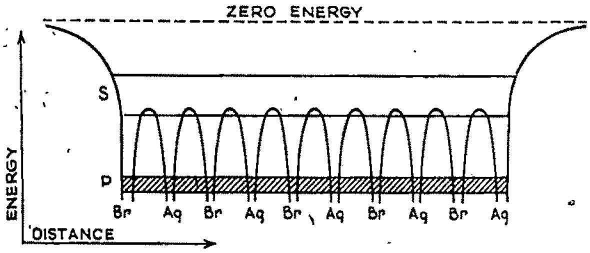

Fig. 1. ENERGY DIAGRAM OF A SILVER BROMIDE CRYSTAL.

mustard oil in an emulsion is very small. A ton of emulsion contains only a couple of drops, and the evidence for the existence of the sulphide specks is therefore indirect.

When Sheppard found that the sensitizing specks consist of silver sulphide, he and his colleagues advanced a theory of the action of light which they called the 'concentration speck theory'. The silver sulphide specks, they suggested, are formed on the surface of the silver bromide crystal and must in some way enter into the lattice of atoms of which the crystal is composed. They produce strains in the crystal, therefore, and these strains stretch into the surface of the crystal as an area of weakness. When light falls on such a crystal, energy travels through the crystal until it reaches the boundary of the speck. At this boundary, owing to the sudden change in structure, metallic silver is set free from the silver bromide. The sensitizing speck thus acts as a nucleus for collecting or concentrating the energy throughout the whole area of the crystal and for liberating metallic silver at the speck itself.

There was still wanting a mechanism for the operation of this concentration speck theory. Such a mechanism has been supplied by the work of Dr. R. W. Gurney and Prof. N. F. Mott and of Dr. J. H. Webb. In the first place, if we consider the energy diagram of a silver bromide crystal as a whole (Fig. 1), there are two energy levels of importance in the photographic process, the *S* and *P* levels, in which the electrons may be situated. The *S* band is normally empty and is referred to as a 'conduction band'. The *P* band is normally completely filled with electrons. Upon exposure of a silver bromide crystal to light which is absorbed in the long wave-length end of the characteristic absorption band, the electrons are transferred from the lower *P* band to the *S* band, and the crystal becomes conducting. This property is well known in other materials, as well as in silver bromide, as 'photo-conductance', and the silver bromide crystal exposed to light may be imagined to be filled with a sort of gas of conducting electrons. This is the primary photographic process—the thing that happens instantly when light falls on the crystal (Fig. 2). When the electrons set free in this way reach a sensitivity speck, either consisting of an impurity or of the silver sulphide derived from the gelatin, the electrons will be trapped and the sensitivity speck will become negatively charged by the electrons that it has absorbed.

In a crystal there are always mobile silver ions in the silver bromide lattice, and these silver ions will travel through the crystal until they reach a sensitivity speck, and there the charge on the ion will be neutralized by the negative charge on a trapped electron and the silver atom freed by the discharge of the ion will be deposited at the sensitivity speck, so that the electrons set free into the conductivity level by the original exposure to light are eventually transformed into silver atoms deposited on a sensitivity speck. This theory postulates that the production of an image by the action of light occurs in two stages: first, the release of free electrons which occurs instantaneously, and then the transfer of the free electrons by neutralization through the silver ions into silver atoms at the sensitivity specks.

This theory of Gurney and Mott supplies a mechanism for the phenomenon known in photography as the 'failure of the reciprocity law'. Bunsen and Roscoe found that, for the photochemical production of hydrochloric acid, time and intensity were reciprocal. That is, the production of hydrochloric acid was independent of the rate at which light energy was supplied and was dependent only on the total amount of energy. In the case of photography, however, it is well known that the effect of light is not independent of the rate at which it is supplied. There is an optimum rate for the formation of the maximum amount of photographic image, a rate corresponding to an exposure of a small fraction of a second. If the exposure is much greater than this—an hour, for example—two or three times more energy may be required to produce the same density of deposit. On the other hand, if the exposure is much shorter—a ten-thousandth or hundred-thousandth of a second, for example—somewhat more energy will be required. In order to account for the inefficiency of very low intensities of light in producing an image, it must be assumed that the silver atoms formed at the sensitivity specks can easily be lost in the early stages of the formation of the image by acquiring a positive charge owing to thermal action. Thus, for example, newly liberated silver atoms would be more easily lost than those which have entered a silver crystal lattice to form metallic silver.

On the other hand, with high intensities of light the electrons are supplied too rapidly, the silver ions do not have time to reach the sensitivity specks by diffusion through the crystal, and some of the electrons are repelled from the highly charged sensitivity specks before they can be neutralized. Much light has been thrown on the nature of the reciprocity failure by a study of the formation of the image at different temperatures.

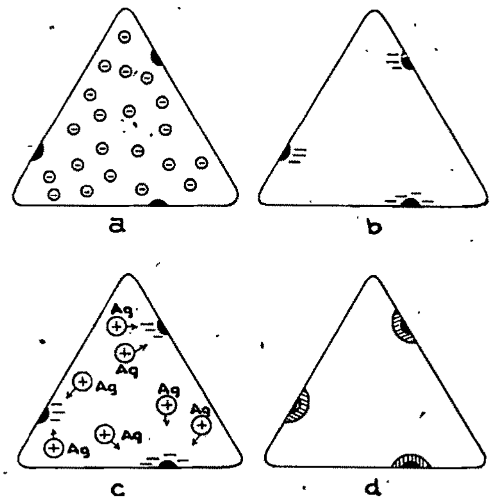

Fig. 2. ACTION OF LIGHT UPON A SILVER BROMIDE CRYSTAL. (*a*) LIBERATION OF ELECTRONS INTO THE CONDUCTING LEVEL. (*b*) CHARGING OF THE SENSITIVITY SPECKS BY THE LIBERATED ELECTRONS. (*c*) MIGRATION OF SILVER IONS TO THE CHARGED SPECKS. (*d*) DEPOSITION OF SILVER ON THE SPECKS TO FORM THE LATENT IMAGE.

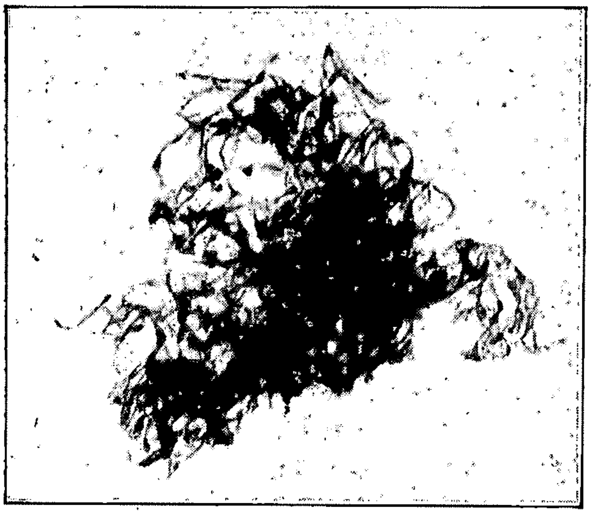

Fig. 3. ELECTRON MICROGRAPH OF A GRAIN OF DEVELOPED SILVER. ×50,000.

The metallic silver deposited at the sensitivity speck and forming a nucleus which facilitates development is what has been known in photography from the earliest days as the 'latent image'. There has been much discussion as to the nature of the latent image, but there is now no question that it consists of metallic silver concentrated at local points in the silver bromide crystal. If the silver bromide is exposed to large amounts of light, a visible discoloration takes place, and this undoubtedly consists of metallic silver. This can be shown by the use of the X-rays in the ordinary crystal structure analysis, when characteristic rings of silver crystals are obtained, and also by the examination of the image by means of the electron microscope, when it can be seen to consist of crystals of silver. Inasmuch as the visible image produced by long exposure to light consists certainly of metallic silver, the latent image produced by short exposure is almost certainly of the same nature.

The mechanism of photographic development has always been very obscure. The general theories as to the nature of development until quite recently were those which conceived it as being similar to crystallization from a supersaturated solution of metallic silver. In the absence of nuclei, deposition of silver would be delayed, and this would check further solution of the silver bromide. In the presence of a latent image nucleus, deposition of silver is facilitated and the solution, reduction and deposition of the silver bromide continues until the crystal is converted into metallic silver. There are many physico-chemical difficulties in this mechanism, but it would undoubtedly have continued as a possible explanation of development had it not been for the evidence recently supplied by the electron microscope as to the form of the silver produced in development.

The silver grains of the developed image are very small and the microscope is unable to distinguish any appreciable structure in them, so that in spite of some suggestions that the silver might be formed as filaments, the general view was that the developed silver grain was a spongy mass of silver crystals somewhat resembling a lump of coke. When developed silver was examined with the electron microscope, however, it was at once seen that the silver grain is a tangled mass of ribbon-like filaments looking very much like a mass of seaweed (Fig. 3). This is not only very important for the light that it throws on the actual structure of the developed image, but also it at once becomes necessary to account for the production of such an unusual form of silver in the development of the silver bromide. Clearly, the supersaturation theory of development will not do at all. It might be thought that the filaments are formed in cracks in the crystal, but this was disposed of by an examination of the very small crystals of so-called 'Lippmann emulsions', crystals too small to be seen in a microscope. With the electron microscope, these appear as normal silver bromide crystals, but when they are developed, each of them turns into a single filament of silver, these filaments being much longer than the diameter of the crystal from which they were formed. The impression, therefore, becomes overwhelming that the silver filament is formed by ejection from the silver bromide crystal. It is squirted out during the process of development from the solid crystal, and the picture we form of the development reaction is that the reducing ions of the developing agent attack the silver bromide crystal, and in some way the initiation of the formation of metallic silver is facilitated by the presence of the latent image speck.

The mechanism for this is supplied if we consider the potential at the surface of the silver bromide. The surface of the silver bromide grain itself has an excess of bromide ions, which give rise to a negatively charged surface. However, just outside this negative charge, a positive layer of potassium ions must be present to neutralize the negative charge. Without such a neutralizing layer of positive ions, it would be impossible for the surface of the silver bromide grain to be covered with negative bromide ions, since the amount of such a charge in so small a region would give rise to explosive forces. A double-charge layer, consisting of negative bromine ions on the grain and positive potassium ions in the gelatin just outside, may be considered to exist around the surface of each silver bromide grain (Fig. 4). Grains with such a double layer (in a solution) would move under an electric field as negatively charged bodies, since the negatively charged grain would be forced in one direction by the field, and the surrounding movable positive-ion layer in the opposite direction; but since at any point in the liquid there would be positive ions to form the surrounding positive shell, the

double-charge layer would be maintained. That the surface charges on the particles and surrounding charge layers do neutralize each other in the manner outlined is proved by the fact that the colloidal suspension does not possess a net charge of either sign but is neutral as a whole.

It may be assumed that a grain, owing to its double-charge layer, behaves toward outside charges and also those located inside the grain as a neutral body. An electron placed inside such a double-charge layer would experience no force nor, in the same way, would an electron placed outside such a double layer. However, there is a marked difference in potential between the inside and outside of the grain, and the total jump in this potential occurs in the region between the two charge layers. The potential gradient between these charge layers accordingly gives rise to a strong electrical force between the layers, and an electron placed between them would experience a force toward the outside. It is considered that the double-charge layer acts in this way as an effective potential barrier to the entrance of an electron into the silver bromide grain of the emulsion and prevents the developer from attacking the grain.

The conditions existing in the exposed grain containing a latent image silver speck may be seen in Fig. 5. This shows a greatly enlarged scale model of a charged grain surface with a clump of silver atoms on the surface, which is supposed to represent the latent image produced by exposure to light. The clump shown includes 220 atoms, with approximately the correct spacing. This size was chosen as representing a fair mean of the values given by various workers.

J. H. Webb assumes that development of a grain is initiated by the break in the double-charge layer caused by the silver speck, permitting the negative developer ions to reach this silver speck. The latent image speck is viewed as an electrode penetrating into the grain. The tendency on the part of the developer ions to release electrons to the silver causes electrons to pass to the electrode and charge it negatively. As explained by Gurney and Mott, this occurs if the electrons of the developer ions are situated in levels above the highest occupied energy levels of the silver metal. The penetration of this negative electrode into the silver bromide grain upsets the neutral electrical condition previously existing in the grain, and there arises an attractive force for the positively charged silver ions in the neighbourhood of the latent-image speck.

Positive silver ions always exist in the crystal lattice owing to temperature motion, and these diffuse to the speck under the attraction of the negative charge there and enlarge the silver speck. Thus, it is supposed that the original silver speck of the latent image continues to grow by this mechanism. As this proceeds, the protective double layer is more and more ruptured, and a rapidly increasing area of the silver halide grain is exposed to the attack of the developer. Since the reduction of silver bromide by a developer is exothermic, considerable amounts of energy are liberated at the boundary between the silver and the silver bromide, while the local rise in temperature facilitates the migration of silver ions, so that the metallic silver is extruded as a filament.

The process of development itself involves certain requirements as to absorption and catalysis of the development reaction, which explain why one substance is a developer and another reducing agent having approximately the same reduction potential is not a developer. Much work remains to be done on the chemical reactions involved in development, but the knowledge which has recently become available as to the formation and nature of the latent image and its function in promoting the development of the silver halide grain has enabled us to form a much clearer picture of the phenomena of the photographic process than was possible previously.

EFFICIENCY AND OUTPUT IN AGRICULTURAL SYSTEMS*

By Prof. A. W. ASHBY
University College of Wales, Aberystwyth

THE measurement of outputs of agricultural systems and their valuation are always a complex proceeding, and the results of any methods of measurement and valuation which have been used up to the present time are to some extent indefinite. Outputs vary in their physical and biochemical characteristics, and in their human uses and values. The only common measure of outputs of varied characters is their

---

[*] Excerpts from a paper read before the Royal Society of Arts on November 11.

money value at any given time. Relative prices of one product and another vary from time to time, and therefore the values of outputs of given quantities of products also vary. A system or type of farming which may be shown to be efficient at one period may prove to be relatively inefficient a short time later, due solely to changes which have occurred in markets.

In any economic and social system which is subject to major changes, adaptability to changes in markets for produce, in industrial production or commercial offers of the raw materials used and usable in agriculture, in industrial production of agricultural equipment, in supply and costs of human labour, must always be a test of farming efficiency. It may, indeed, be the acid test from which there is no hope of anything except a very temporary escape. There is scarcely any major change in the economic and social institutions and conditions of a nation which does not, sooner or later, affect forms of organization for agricultural production and their results.

A quarter of a century ago many essays were made to judge agricultural systems on their outputs of food values—in carbohydrates, fats, and proteins—in the common measure of calories. But modern knowledge of nutrition, by adding vitamins and minerals to the elements expected in food supplies, has severely qualified these tests. There is no common measure which can be applied to all the food values of the products of any two or more agricultural systems.

But even when we thought we were able to measure and value agricultural outputs in physical and biochemical terms, we were quite unable to measure inputs in these terms, and therefore were unable to judge the efficiencies of systems of production. The 'calorie' test was usually only quoted per acre of land, which itself is more a measure of superficial area than of productive capacity, and any other test was rare. A simple illustration of this test shows its weakness.

The order of yields of calories and of protein per acre, of the following crops, in human use of the main products and of the secondary products of their by-products is :

	Calories per acre (order)	Protein per acre (order)
Sugar Beet	1	3
Potatoes	2	1
Wheat	3	2

While wheat and pig-meat produced by the offals give less than 45 per cent of the yield of calories obtained from sugar in sugar-beet and milk from tops, they give nearly three times the protein yield. But when the test of production per man-hour of labour is applied the order is entirely changed :

	Calories per man-hour	Protein per man-hour
Sugar Beet	3	3
Potatoes	2	2
Wheat	1	1

Wheat gives much the largest return of energy per unit of manual labour—nearly three times the return of protein when compared with potatoes, and about eight times the return of protein when compared with sugar-beet.

We may, indeed we must, occasionally apply the physical and biochemical measures to agricultural outputs in relation to human food requirements or supplies. But they are only crude tests of efficiency in feeding the nation. They are not tests of efficiency in production.

Every nation at any time, and particularly in war-time, must seek to make the optimum use of each and all its resources ; and the maximum use of land, maximum production per acre, tends to waste human energy everywhere. It nearly always wastes sweat, and not uncommonly blood and tears. A nation which has a very dense population, or a dense population tending to increase, and few resources other than its surface soil, may have no option but to seek maximum use of land, and highest possible production, but such a nation is to be pitied rather than envied. Or, in these days of close international relationships, we should say : pitied and assisted to find other outlets or uses for labour.

The general principle is that each nation will determine its standard of production per acre of land in relation to two main conditions : (1) the existence of other resources or means of useful employment of population ; (2) the standard of remuneration and of living established for workers in industries other than agriculture. When full examination is made of the economic and social conditions of nations with high density of agricultural population and high production per acre, it will be found that they adopt these conditions of necessity rather than choice. If they had other resources on which to use labour, they would modify their agricultural systems.

Efficiency, whether of motor-cars, of cows, or of crop-acres, is always measured by the ratio of output to inputs. Outputs are the results of inputs, with some factors, such as weather, which may be beyond the producer's control or even influence. Inputs are determined by the technical knowledge and the capital resources of the farmer and according to his judgment of the money costs and the money values of the expected result in outputs. Every single input may be applied with different degrees of economy and efficiency.

The main inputs are land, human labour—manual and managerial—and capital. But capital takes many concrete forms—in live and dead farming stock and materials. If we wish to apply even simple tests of efficiency of farming systems we must test production (*a*) per unit of land, (*b*) per unit of labour, (*c*) per unit of capital. We must also test by the best combination of measures of these inputs that we can find. For this purpose each has to be valued and measured in money.

The productive capacity of land or farms in Great Britain is far better measured by money values as rentals than by superficial area. The productive capacity of two acres in different districts may vary as much as 100 : 1 and commonly varies as much as 25 : 1. Rental values tend to represent and to equalize measures of productive capacity. There is no other common measure of all the geophysical conditions which influence the productive capacities of different units of land as such.

The technical conditions of choice and application of some of the embodiments of capital, both fixed and circulating, are too varied for general discussion. But some conditions may be indicated. The efficiency of power sources and of implements and machinery has been rising. It appears that the input of feed required to produce a gallon of milk has fallen by about one sixth in this century because of selection of breeds, strains, and individual animals, and greater knowledge and better practices in feeding. The feed required to produce a given weight of mutton or lamb, and the time and probably the feed required to produce a 10-cwt. fat bullock, have also been reduced.

The amount of feed required to produce a dozen eggs has been reduced by some 12–15 per cent. There is also evidence of rising efficiency in crop production.

The best simple measure of the general rise of efficiency is found in the output per man, which has probably risen about 70 per cent in the last seventy years. From 1925 to 1939 the increase was very rapid. Different criteria of efficiency may be applied by interested parties. If agriculturists as a community have to apply any single standard to production they will judge it by the net output per man (gross output less cost of raw materials and depreciation of equipment), for it is this which determines the possibilities of their standards of remuneration and of living. Having set a high standard of output per man, each class can bargain for its distribution with the assistance of any social forces they can draw to their aid. But with a low standard of output the standard of remuneration of one or more of the classes, and possibly all, must be low.

The general practice seems to have been to make international comparisons mainly in terms of yields or outputs per acre. But recently there has been a change, and other tests have been applied. On the information now available, it appears that Great Britain will take different positions in an international order of productivity according to the test applied. In a list of twelve countries—New Zealand, Australia, Great Britain, U.S.A., Denmark, Canada, The Netherlands, Belgium, Switzerland, France, Germany, Eire—the position of Great Britain is : (1) value of output per acre, seventh ; (2) persons fed per acre (on cash value basis), sixth ; (3) persons fed per worker, third (excelled only by Australia and New Zealand) ; (4) value of output per worker, third (again excelled only by New Zealand and Australia). In a test with seven European countries—Great Britain, Germany, France, Denmark, Belgium, The Netherlands, and Switzerland—the position of Great Britain is : (1) value of gross and net output per acre, seventh ; (2) value of output per worker, first ; (3) average income per whole-time person engaged, almost certainly first.

But in case there is a tendency still to judge yields or outputs per unit of superficial area of land, that is, per acre, it may be pointed out that among the seven European countries, Great Britain is second only to Denmark in gross output per pound sterling annual (rental) values, and second only to France on net output per pound sterling annual (rental) values when a standard rate of interest is applied to capital values of land in each country. The rate of interest on capital values represented by gross rents or prevailing rates of interest on mortgages is higher in Great Britain than in any of the European countries listed. Measuring gross and net outputs against annual values of land as determined by the prevailing interest rate in each country, which varies between about 2·2 per cent in Belgium and about 5 per cent in Great Britain, this country stands fourth in the list.

If Great Britain wishes to retain an agricultural population, which will be satisfied and satisfactory from either economic or social points of view, it will continue to be necessary to maintain a high standard of net output per worker, and all other standards have to be fitted to this condition. Even in war-time we have to make the optimum use of labour ; we cannot afford to waste labour on unproductive land ; we must use our labour where it will be most productive of the supplies of which the nation has the greatest need.

The nation will judge by the quantities and qualities of products offered for human use and consumption in relation to its requirements, normally expressed through the markets, but in war-time expressed through the administrative organs of the State (Ministries of Agriculture, Food and Supply). Beyond this the nation has never had any clear criteria. The interested but poorly informed public has many and often conflicting criteria. It wants reasonably cheap food, maximum employment of labour, maximum production from the land, more small holdings, higher if not maximum wages and better housing for farm workers. It wants more wheat for national defence, more milk and vegetables for health, more eggs and more and higher quality meats to stimulate appetites and to meet needs due to changes in industrial work, urban living, and standards of real incomes.

Specific tests are applicable for special purposes in certain circumstances. The agricultural system of each country is more or less fitted to its general economic and social conditions. The conditions established in one country are not necessarily to be sought by any other, and the standards applied in one country are not likely to have any real validity in any other, unless the general economic and social conditions are similar in both.

Perhaps the most acute controversy about standards of production and efficiency in the future will turn on the efficiency of large farms. Past studies of the smaller and larger farms in Great Britain have usually shown that the smaller farms had the higher outputs per acre and the lower outputs per man. But in any discussion of this problem it must be remembered that few of the large agricultural enterprises in the country have been organized on unitary holdings, and also that there is no public information on the details of organization, inputs and outputs of the best of the large enterprises in Great Britain. Before any firm judgment can be made on the relative economic and social results of the largest, the medium and the small enterprises, we need much more information on the largest enterprises. At present information is practically limited to the small and medium-sized businesses.

A further caveat must also be entered. Even if it were proved that the results of the larger enterprises now in existence are not any better than those of the medium-sized or other groups, that would not prove that large unitary enterprises could not be designed, organized and operated to yield highly satisfactory results.

GEOLOGICAL MAKING OF INDIA

MR. D. N. WADIA, author of the well-known "Geology of India for Students", retired from the Geological Survey of India in 1938, and shortly after took up the appointment of mineralogist to the Government of Ceylon. He was president of the Geological Section of the Indian Science Congress at its jubilee session in Calcutta in 1938, and became general president of the whole Congress at the twenty-ninth session held this last January at Baroda ; he is the third geologist to fill this position. During his Indian service Mr. Wadia was engaged mainly in the study and mapping of the post-Archæan folded formations of north-western India, including Kashmir. In his present service, in Ceylon, he has been called upon to study the rocks at the other end of the geological scale, forming the Archæan basement. This exceptional diversity of opportunity has enabled him in his presidential address to the Indian Science Congress (Proc. 29th Ind. Sci. Cong., Part II, 3–23; 1942) to discuss with wide experience the "Making of India", in which he makes particular use of data derived from Ceylon, which, of course, is only a detached fragment of the Peninsula of India.

Mr. Wadia emphasizes the well-known general distinction between (1) the geologically speaking, recently folded extra-peninsular area of India, comprising the mountain festoons of Baluchistan and the North-West Frontier on the west, of the Himalaya to the north, and of the Assam-Burma ranges to the east; and (2) the geologically ancient and stable Peninsula, with its Archæan basement, superposed Purana and Gondwana sediments, and Deccan Trap basalt flows, and the absence of any serious folding movements since pre-Cambrian times. Such mountains as now exist in the Peninsula of India are either deeply eroded remnants of pre-Cambrian ranges, such as the Aravallis and the Eastern Ghats, probably (in the reviewer's opinion) re-elevated, or are plateau mountains due to denudation, with block uplift and depression, as in the Deccan Trap section of the Western Ghats.

In the extra-peninsular area, compressive earth forces still prevail, as instanced by the frequency of serious earthquakes; while in the Peninsula tensional forces with vertical uplift and depression have long prevailed, and serious earthquakes no longer occur. This essential difference between the extra-peninsular and the peninsular areas of India was noticed by W. T. Blanford, in the first edition of the "Manual of the Geology of India", so long ago as 1879, and was recently emphasized by myself (*Rec. Geol. Sur. India*, 62, 408; 1930). As Mr. Wadia points out, this fundamental difference between the two main portions of the Indian sub-continent is due to the fact that it is composed of two crust-blocks of totally different history, namely, the Archæan shield of the Peninsula, which is a fragment of Gondwanaland; and the folded belt of the Himalaya representing the Tethys, which by their interaction have produced the Indo-Gangetic plains.

In Ceylon, the whole island is occupied by an Archæan crystalline terrane, except for Miocene rocks occurring mainly as a fringe on the north-western edge, and a minute occurrence of Jurassic rocks. The central portion of the island is mountainous, rising to 8,292 ft. in Pedrotallagalla. Three well-marked terraces or peneplains have been described by Prof. F. D. Adams, and are recognized by Mr. Wadia. "These three terraces rise from the sea in two sharply cut steps or escarpments, the lower step about 1,000 feet above the coastal peneplain (which is very nearly a plain of marine denudation) and the second step 3,000–4,000 feet above the latter to the third and highest peneplain" (p. 14). These escarpments are characterized by numerous waterfalls.

There are two possible explanations of these terraces. They may represent successive levels of denudation, in which case the lowest terrace is the youngest, and all that is required to explain this peculiarity in the orography of Ceylon is successive uplifts of the island as a whole, the mural scarps being due to the effects of differential erosion on beds of different powers of resistance. Or the terraces may be due to selective block uplift, and the mural scarps represent eroded fault scarps. The coastal terrace is then the oldest, and the mountain centre of the island the region of latest uplift. Adams, in his study of the geology of Ceylon (*Canadian J. Research*, 1, 425–465, 467–511; 1929), adopts the former explanation, and Mr. J. S. Coates, who was Mr. Wadia's predecessor as Government mineralogist, does not disagree with Adams in his "Geology of Ceylon" (*Ceylon J. Sci.*, **19**, Sect. B, Part 2, 101–186; 1935); nor does Coates's geological map, which is admittedly only a sketch map, show any necessity for block faulting. Mr. Wadia, in his address, discusses only the second possibility and states: "The field geological work so far carried out in this area indicates, beyond doubt, that the Ceylon mountains are not the undenuded passive remnants left out of an old table-land, but have been 'created' by positive earth-movements, lifting them vertically in two intermittent, widely separated stages". In his view the second peneplain was elevated in post-Jurassic times, and the uppermost and central terrace in late Tertiary times.

In the absence of the evidence upon which Mr. Wadia bases his belief in selective block faulting, it is difficult for the reader to judge between these two possibilities. Adams's explanation seems so reasonable that the reader will probably prefer to follow him until Mr. Wadia produces his evidence, which he has deferred to an occasion more suitable than an address to a general audience. Should Mr. Wadia's detailed account carry conviction, then the credit for establishing this hypothesis of selective block-uplift to Ceylon will belong to him.

In his general discussion of the making of India, Mr. Wadia raises many points upon which there is scope for difference of opinion; lack of space prevents reference to them all. It is necessary, however, to demur to two passages in particular, namely, that (p. 9) which speaks of the "unpuckered and generally horizontally bedded rocks" of the peninsular crust-block of India, and the statement that Mount Everest is built of "this axial granite core". Many of the Archæan gneisses and schists of the Peninsula are as contorted and crumpled as any in the Himalaya; while Mount Everest has been shown by Odell and Wager to be composed largely of metamorphosed sedimentary rocks.

In the first part of his address, devoted to general matters, Mr. Wadia discusses the interactions of science and industry in India, and also the charge against science of "helping with its inventions and discoveries man's lower instincts and lust for power, possession and aggrandizement". This misuse of science is, of course, not due to the scientific man as such, and to check such perversion Mr. Wadia states (p. 5) that "it is time the hierarchy of pure science asserted its patent rights on the common pool of strategic science and, backed by its 1½ centuries of resolute strivings for the betterment of mankind, claim a determining share in the governments of the world. An international directorate of scientists, containing a due proportion of economists, engineers and industrialists, will, by adopting the technique and temper of science, govern the countries of the world better than the chancellors, diplomats and politicians who for the past 5,000 years have failed to bring harmony in human relations, but have signally succeeded in making history one record of recurrent wars." L. L. FERMOR.

MECHANISMS OF VISION

Visual Mechanisms

Edited by Prof. Heinrich Kluver. (Biological Symposia, Vol. 7.) Pp. viii+322. (Lancaster, Pa.: The Jacques Cattell Press, 1942.) n.p.

THIS volume is the outcome of a symposium on "Visual Mechanisms" organized in September 1941 for the celebrations of the fiftieth anniversary of the University of Chicago. It is in twelve chapters, each written by specialists engaged in research on particular aspects of vision and each dealing with the advances and outstanding problems in a special field. With such a composition it might well have become no more than a series of disconnected reviews, but the authors and editor have made it into something which can be read straight through with pleasure by anyone interested in vision. Careful arrangement of the subject-matter is partly responsible, for we are led by easy stages from the material to the mental, from the photochemical reactions of the retina to the problems of visual recognition and learning. Thus the first chapter is by Selig Hecht, written with his usual lucidity, on the number of quanta needed for visual sensation. The chemistry of the visual pigments is dealt with by A. C. Krause and George Wald, there is a middle section on the activities of the visual pathways as they are revealed by electrophysiological techniques, and this leads up to the discussions by Lashley and Klüver on the way in which visual stimuli can be supposed to determine behaviour.

The book is a record of rapid progress made in the last few years, mainly along lines opened up by new techniques of physics and chemistry. The lines of advance were often unexpected and some of the classical problems of vision are not much nearer solution. There is no chapter on colour vision, for example, and probably there would not be much excuse for one, although Hartline and Granit have added significant data. But to compensate there is a valuable discussion of the factors determining visual acuity by Marshall and Talbot, based on the new electro-physiological methods. One of the basic (but seldom discussed) problems of vision is how we see, sharply defined, a straight line the geometrical image of which subtends in width only a small fraction of a retinal receptor. Marshall and Talbot have mapped the visual cortex in monkeys and have found that for the fovea the pathway from each cone expands on its way to the striate area, giving probably a direct connexion with a hundred cortical cells apart from any spread due to cross connexions at different levels. Thus the cortical mosaic has a much finer grain than the retinal; and they show that for a variety of reasons it is the cortical mosaic and not the retinal which decides the acuity of vision, the retinal mosaic being discounted by eye movements as well as by diffraction, while the cortical contrasts are intensified in a way which restores the sharpness of outline. In another chapter Bartley considers brightness discrimination from the same angle. Neither of these contributions makes easy reading, but arguments about neurone systems must always suffer from the complexity of the events with which they deal. Both chapters are certainly worth study as evidence that the analysis of activity in the units of the nervous system has already given place to attempts at synthesis, to the formulation of principles governing the distribution of activity in large groups of interconnected units. In the brain the messages from sense organs are not projected on a blank surface, but on one with a constantly changing activity of its own. We can begin to see what sort of interactions can occur and how the whole field may influence what happens in a limited arrival area: in fact the gap between the nerve impulses of the physiologist and the total configurations of the psychologist seems no longer immeasurably wide.

The two psychologists whose chapters end the book have never treated the gap between physiological and psychological aspects as if it were too wide to be contemplated with decency. Lashley has been concerned with it throughout his work and has made it far less formidable by defining the main obstacles. In this volume he deals particularly with the problem of learning and of 'stimulus equivalence'. What sort of physiological mechanism can explain our recognition of the letter A whenever we meet it? What we recognize is not the stimulation of certain neurones which have been sensitized by repeated use, for the neurones will vary with the size of the letter and its position in the visual field. Lashley rejects various theories but thinks that reverberating circuits in the cortex and interference patterns offer a more hopeful prospect. We must wait and see: meanwhile Klüver's article shows the fallacies of assuming that animals must see things as we do, and shows the careful analysis of behaviour which is essential before we can argue from the monkey to man.

Klüver rightly stresses some of the dangers of the comparative method when we are dealing with the visual system as a whole, but there is no doubt of its value when we are concerned only with the receptor apparatus. The descriptions of the anatomy of the retina by Walls and Polyak illustrate this and so do the chapters on the chemistry of the visual pigments. Wald's deals particularly with the relation of rhodopsin to vitamin A (a relation which Krause treats with some reserve), and the zoologist will be specially interested in his account of porphyropsin, the pigment in the eyes of freshwater fish, related to A_2 as rhodopsin is related to A_1, and of the rhodopsin–A_1 system in molluscs and arthropods.

The volume is worthy of the notable occasion for which it was designed. Though the War may limit its circulation we are deeply indebted to all who have taken part in it, for they have given us a welcome reminder of some of the fundamental problems of science. E. D. ADRIAN.

TEMPERATURE CONTROL

Temperature Control

By A. J. Ansley. Pp. viii+126+6 plates. (London: Chapman and Hall, Ltd., 1942.) 13*s*. 6*d*. net.

ANY regular reader of a journal devoted to physics, or to scientific instruments, or to chemistry or to industrial chemistry, will find several articles each year in which a thermostat or controlled-temperature bath is described. In the view of its author, each of these new designs is superior to any of the old ones, and in fact they usually incorporate improvements, and are usually particularly suited to the problem in hand. Given then this vast mass of literature, it is certain that an investigator confronted with the problem of building a thermostat system for himself will find it difficult to make a choice among the various systems unless he can have guidance from someone more experienced.

It is to meet the needs of such people, as well as of general students, that Mr. Ansley has written this book on temperature control, and no doubt it will be helpful to many. It deals, rather shortly, with all the main types (expansion of liquids, expansion of solids, vapour-pressure type, and so on) and frequently gives practical hints of great value. Nevertheless, it cannot be unreservedly recommended. The theoretical background is often given in a confusing manner, almost as though the author did not understand it himself, and there is in many cases an apparently deliberate departure from any logical order. Thus, on the first page, we find a section devoted to "Control Unit Terms", the first of which is "The Differential". Instead of being told at once what this is, we are informed that it "is most conveniently provided by immersing the apparatus . . . in a bath . . .". The next term, "Hunting", is explained in a way that gives it a different meaning from that usually associated with the word, and goes on (still under the same heading) to "The points to be remembered in control design are : . . .". Again, on p. 5, there is an explanation of vapour-pressure instruments which seems to imply, wrongly, that the pressure of the vapour depends on the size of the bulb. The function of the cone in a sulphur bath is not protection of metal against attack by sulphur, but to act as a radiation shield. The hydrogen in a barretter is introduced on account of its thermal conductivity and not primarily to prevent oxidation.

In addition to these major slips, there are far too many minor ones. Constantan is consistently spelled 'constantin', we are advised to use leads of 2 sq. cm. cross-section in thermocouples, the boiling point of sulphur is given on p. 29 as 445·5° and on p. 10 (where it is called the melting point) as 444·6°, the true value being 444·6°. In the table of coefficients of expansion, it is surprising to find that invar, with a higher coefficient than iron or copper, has been selected as typical.

Finally, it would be unfair to scientific workers in general if we did not point out that the grammar and style are much worse than we expect or are satisfied with. In this respect, as with the last-mentioned error and with the placing of a diagram upside down, the author has been badly served by his proof readers. They should have noticed some of the many occasions where a subject fails to agree in number with its verb, and they should have pointed out, when the author wrote " . . . it is feasible to suggest that . . ." that it is *feasible* to suggest anything whatever. They could, too, have saved him from many clumsy sentences ; for example, "This oxide not only increases the contact resistance, but renders renewal frequently or cleansing of the mercury essential. Various attempts have been made to minimize this defect by providing a protective film of oil, such as glycerine for the mercury, but after some period of use it will not be found to have improved the control".

No doubt the book has been written in difficult circumstances, and this explains many of the blemishes, but the fact remains that the book is not as good as we could have expected from this writer. However wholesome the diet, our attention is distracted from its goodness, and our appetite spoiled, by the unattractive way in which the dish is served.

J. H. AWBERY.

WEATHER STUDY IN THE UNITED STATES

Weather Elements

A Text in Elementary Meteorology. By Prof. Thomas A. Blair. (Prentice-Hall Geography Series.) Revised edition. Pp. xvii+401. (New York : Prentice-Hall, Inc., 1942.) 5 dollars.

JUDGING by the fact that this book has been reprinted five times since its first publication in April 1937, and has now been revised, it has proved very popular in the United States. The public interest in meteorology is probably much greater there than in Great Britain ; for one thing, the atmospheric phenomena are often more violent, culminating in disastrous tornadoes, floods or droughts, and the more specialized agriculture is so organized that favourable or unfavourable weather may make the difference between wealth and comparative poverty to a large agricultural population. In England our famous 'samples' are more easily balanced out by the more diversified farming. Secondly, in recent years the rapid growth of civil aviation has given many people an interest, amateur or professional, in the weather. Finally, the average American appears to be more addicted to the accumulation of varied knowledge than his equivalent in Great Britain ; he is more ready to spend money on relatively expensive books, but in consequence he prefers a book which can be absorbed quickly and does not call for prolonged and intensive study.

Blair's "Weather Elements" meets all these needs admirably. It is attractively got up ; it is full of interesting information reduced to a few lucid paragraphs on each subject ; there are plenty of illustrations including some excellent photographs, and it is very easy to read. The intelligent member of the public with little physics and no mathematics will find it ideal. For the serious meteorologist it is less satisfying, for though it is very good so far as it goes, it does not go nearly far enough.

One example will suffice. The chapter on "World Weather" contains, among others, sections on "Frequency curves" and "Correlation coefficients and regression equations". The first gives two frequency polygons, with values of the mean, median and mode, but no attempt is made to explain the two latter terms. The polygon of 65 January rainfalls at Cleveland by steps of 0·2 in. is highly irregular ; an isolated maximum at 1·40–1·59 in. is called the 'mode', but the reader is not warned that the record is too short to give such minor details any real meaning. Again : "Mathematical considerations also enable us to determine how often the rainfall will fall below or exceed any given amount". It is left at that ; standard deviation is not even mentioned. A correlation coefficient "is computed by a mathematical process which takes account of and compares the individual deviations from average of the two sets of data year by year". There is not an x or y in the book ; nothing, in fact, to break the smooth, even flow of text.

From another point of view the book is definitely written for an American public, in that there are few references to methods or events in other continents. The methods of observation described differ in many important respects from those in use in Europe ; the dry- and wet-bulb thermometers are whirled in a sling instead of being read in a screen, the rain-gauge is read with a dipping rod instead of with a measuring glass, the sunshine recorder is electrical and the cloud searchlight becomes a "ceiling light". The only barometer described is the Fortin, but the description is very sketchy and the illustration useless; the vernier is mentioned, but not described, and there is no indication of its purpose. The U.S. Weather Bureau fog scale is given, but the usual international definition of a fog is not mentioned.

The author is at his best in describing the simple physical processes of weather, and these parts of the book should be of real value to school teachers, who are also provided with a number of ready-made test questions and with several pages of monthly means of temperature and rainfall. There are a few odd statements, such as "Warm and humid air, as in a fog", and that air in crowded rooms suffers from *low* humidity. The chapter on "Climate and Man" contains a good deal of interesting material not usually found in text-books of meteorology, and the last chapter gives an excellent account of the history and activities of the U.S. Weather Bureau, especially in their application to matters like the control of floods or forest fires and the combating of frost damage, which should interest all citizens of the country. There is an excellent classified bibliography of suggestions for further reading.

C. E. P. Brooks.

FOOD AND PLANNING

Food and Planning

By Prof. J. R. Marrack. Pp. 285. (London: Victor Gollancz, Ltd., 1942.) 15*s*.

THE dictum that the scientific man should 'have no politics' is still held to-day by many men of science. It is interpreted variously: that scientific research should possess the worker, excluding all else from his mind; he should have his energies fully occupied in solving his academic problems, and the applications of the results are 'politics', and should be left to others; he would be biased in his approach to an academic problem by an active interest in the practical applications of its solution. It is true the research type of mind is rarely adapted to apply the results socially, unless the biological trend of the investigator's thought is in that direction. The acute struggle for existence of the War of 1914–18 and its post-war period led to governmental organization of the applications of science to everyday problems. The planned surveying of man and his environment increased our knowledge of *Homo sapiens*, and stimulated further investigations. Possibly the main development of science between the two wars is the realization that there is a natural and close interdigitation between the pure abstract problem and its application in industry or human life. The scientific man is not a mental eunuch, but rather a rational human being, whose work must be conducted objectively and fearlessly, and whose reasoning and experiments need to be uninfluenced by conditions of expediency or possible repercussions.

This close connexion between science and the social life of the world's population is possibly most appreciated in physiology, and particularly in regard to nutrition. Prof. J. R. Marrack in this book exemplifies the relation of the research worker to the applications in everyday life. He shows that not only have we knowledge of the nutritive needs of human beings, but also that the bulk of the world's population is by these same standards undernourished in varying degree. If we feel the welfare of human beings is important, then we can, by planning for that purpose, achieve adequate nourishment for everyone in all countries, as Sir John Orr emphasizes in the preface.

The first part of the book deals with the normal foodstuffs, their chemistry and function, and with the physiological requirements of the individual. This elementary physiology is dealt with in a manner different from that of the standard text-book. The emphasis is on the needs and response of man, rather than that of animals. The evidence is new, modern and recent, and the experimental illustrations are culled almost entirely from human experiments, surveys and international experiences. An excellent account is given of the pathological distortions, and of the problems of standards of food requirements.

The next part of the book treats of the applications of this knowledge. Beginning with details of actual peace-time consumption of food in different countries throughout the world, it follows with a clear statement of the evidence for malnutrition and impaired health arising thereby. Next there is described the food consumption in Britain and on the Continent during and after the War of 1914–18, the ill-effects arising, and the administrative steps taken to combat this bad health. The last three chapters deal with the present War, the rationing and the respective policies of Britain and Germany. Finally, Prof. Marrack plans for the future as well as for our present war-time state.

The book is long, and although comprising only 285 pages, it is in small print, and achieves fairly—and sometimes very—detailed accounts. It is written for the educated man with an elementary knowledge of general science, but is essentially non-technical and straightforward, very lucid and always understandable. It is a book that will be frequently utilized by anyone interested in the subject: it is strikingly full of new names, facts, experiments, references and views, but its utility is seriously impaired (quite apart from the war-time price of 15*s*. net) by the complete absence of a list of tables and diagrams, of an index or a bibliography. Different individuals will question different parts, the attribution of responsibility, the weighting of evidence, but this is largely a question of legitimate difference of opinion or inference.

Probably one of the most important contributions of the book is the large body of evidence—physiological, sociological, economic and political—which Prof. Marrack has collected as to the causes of defective food supplies. It is patent throughout that the stimulus of a humanitarian philosophy has incited the author to write this book and to initiate a plan which he feels will improve human welfare. But the one construction of this plan is based on an objective examination of the evidence. It is built up dispassionately and logically, because it is in the best interests of the world to have no obstacles left that prevent the fullest nutritive health. Prof. Marrack further maintains that now, while the War is being fought, is the time to begin planning. "The redeeming sanity of war is that its purpose is clear, and its methods are logically directed towards the achievement of that purpose—can we keep this sanity after the war, and use the working machinery to plan an ordered society in which the needs of the people are the prime object ?" (p. 284).

Prof. Marrack regards the world's food supply as being inadequate, because it is left to an economic system dependent upon a profit motive for its effective working. The breakdown may be in purchasing power, retail price, costs of transport, production, or governmental financial policy. So long, however, as food supply is controlled by factors other than the nutritional needs of the people, so long will that supply be liable to shortages.

Before this War, 90 per cent of the world population was in some respect short of food. The essentials of food planning include increasing the production of food. The biggest obstacles to this in different parts of the world are the small size of farms (33 per cent of farms in Japan are a quarter of an acre in size), debt on the farmer (£40 per head of population in Rumania) and backward state of agriculture (primitive instruments and methods). Planning must include regulation of amounts and type and transport of foodstuffs, and finally increased purchasing power. To attain all this with efficiency, Prof. Marrack proposes an international supreme authority with power to plan on a world scale, using the fullest resources of the globe, and with executive powers to carry its plans to fruition, so that no obstacle shall impede any individual from attaining full nutritive health.

A. ST. G. HUGGETT.

SURFACE PHYSICS AND CHEMISTRY

The Physics and Chemistry of Surfaces
By Prof. Neil Kensington Adam. Third edition. Pp. xii+436. (London: Oxford University Press, 1941.) 22*s.* 6*d.* net.

MANY branches of science have had their seeds planted some forty years ago and in the intervening period have germinated, grown and flourished to such an extent that massive trees now stand on previously bare earth. The physics and chemistry of surfaces is in this category, and the historian follows this growth first by means of a monograph and then with a text-book in which edition follows edition. Prof. N. K. Adam is universally recognized as one of the historians of this subject, and we welcome his third edition of his well-known text-book.

This volume follows the lines of his second edition, in which a few sections have been rewritten and certain important advances have been inserted in an appendix. It must be admitted that this is not a very satisfactory method of presenting an integrated view of the whole subject. Indeed, the fundamental difficulty presented to the historian goes somewhat deeper, in that subjects soon outgrow the confines of a single text-book. It would indeed be preferable to cut once and for all the Gordian knot and divide the subject into discrete sections, for example, into fluid and solid surfaces respectively. The problems of each would indeed be confined, but with difficulty, into the confines of single separate volumes.

The present edition gives an excellent account of the present state of our knowledge of the liquid surface, in which field Prof. Adam himself is a recognized authority, but many advances have been made in the study of gas films on solid surfaces as well as in understanding the mechanism of the various heterogeneous catalytic processes, more particularly those involving hydrogen, such as exchange reactions, hydrogenation, double-bond migration and ring closure in hydrocarbons, which might well have been included in an authoritative text-book.

The space which would be available if these topics were transferred to a separate volume could readily be filled by extension of certain portions of the present volume. Thus on p. 35 some thirteen lines only are devoted to the examination of films by reflected light. This method of examination, admittedly a difficult one, is a powerful method of attack, and several interesting properties of films have been revealed which might well have been included.

The general characteristics of surface films of insoluble materials can be portrayed by means of the phase rule, and the thermodynamics of the equilibrium between phases and changes of state have been shown to follow the three-dimensional prototypes. In ordinary phase changes there is a sharp transition in which the properties change discontinuously, including the area and the entropy (resulting from the latent heat). We know in three-dimensional systems that there are cases in which the change in volume and entropy are not discontinuous but merely change very rapidly within a few degrees; this is revealed by a large specific heat in the neighbourhood, but no latent heat. Such changes as are exemplified by molecular rotation in crystals or order-disorder transformation in β brass are phase changes of the second order. Dervichian, in a lengthy series of investigations, recently showed that such changes were also exhibited by monolayers. More than one page in the appendix might have been devoted to this work.

On pp. 38–39 a general description of the method of presenting the results of measurement of the phase boundary potential at liquid/air surfaces is given, and a further development of the concept of phase boundary potentials at liquid/solid and air/solid interfaces is given in Chapter 8 and the appendix thereto. Gatty's analysis of the phase boundary potential at the liquid/air surface provides us with the clearest picture of the origin of surface potential and should find a place in the introductory chapter.

It is clear that our knowledge of the structure of monolayers of macromolecules, especially of the biologically important proteins, is by no means complete. The author adopts the view that protein films are coherent. Several French investigators, on the other hand, have claimed that the vapour state can be obtained and actually measured, providing us with a method of determining the molecular weight. This clearly requires reinvestigation.

Only two and a half pages are devoted to consideration of the chemical reactions in films and the formation of complexes by the process of film penetration. The literature on this subject is now fairly extensive, and in view of the many biological implications it may be regarded as one of the most important aspects of surface chemistry, fully meriting a chapter to itself.

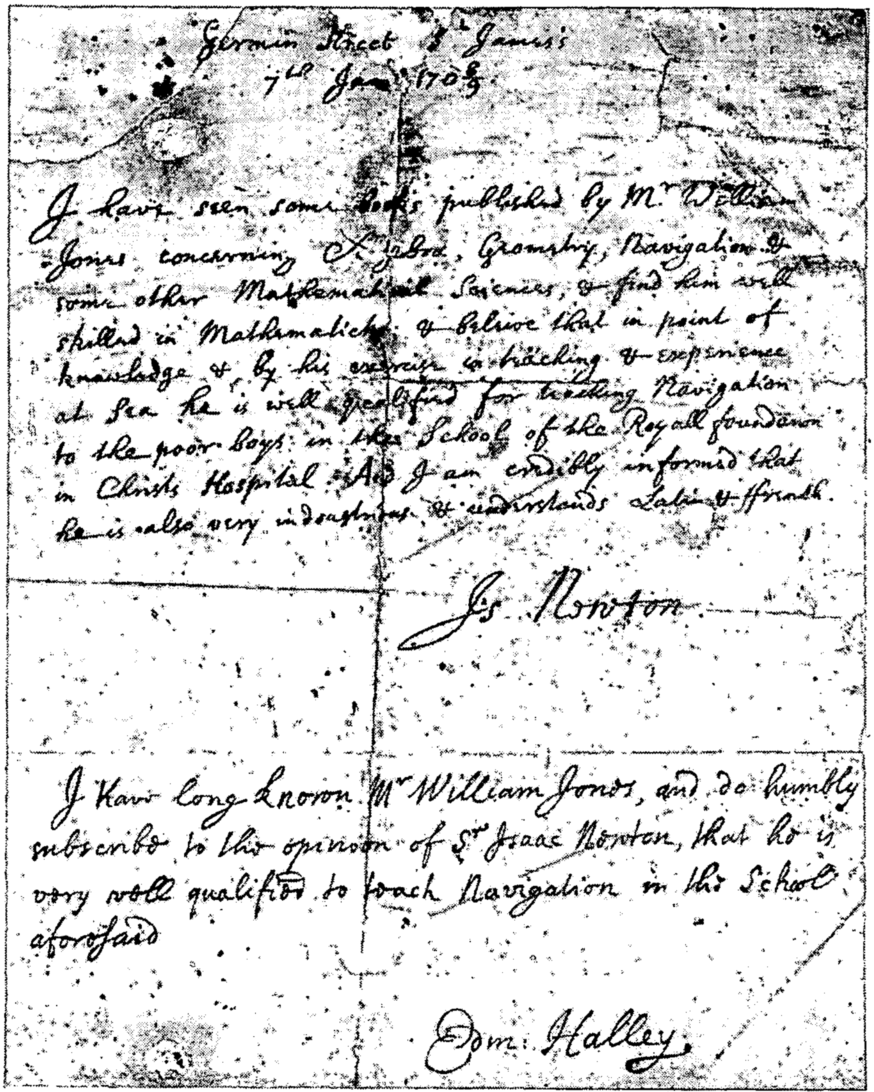
The third edition has been compiled with the author's usual care, and the topics given in the appendix have evidently been carefully selected with the view of presenting important as well as interesting developments in the field of the physical chemistry of surfaces. Scarcely any imprint of war is to be noted in the paper, binding, or printing of this, the third edition.

ERIC K. RIDEAL.

NEWS and VIEWS

Newton's Life and Works

Among the tercentenary celebrations of Newton's birthday was a meeting of the London and Home Counties Branch of the Institute of Physics held on December 9. The meeting was addressed by Dr. H. Buckley, of the National Physical Laboratory, and very appropriately was held in the Royal Institution, where a few days previously the Royal Society celebrations had taken place. Dr. Buckley's theme was "Some Historical Aspects of Newton's Work". He reviewed Newton's life in its relation to his scientific work, bringing out his interest in experimental studies and recounting the development of the papers presented, generally as the result of invitation, to the Royal Society. Speaking of the "Opticks", Dr. Buckley pointed out that, as in the "Principia", Newton develops the subject by the formal method of propositions, each followed by proofs, but whereas in the "Principia" the proofs are mathematical, in the "Opticks" they are accurate and clear descriptions of experiments. An informative account of the fate of the various editions of the "Principia" was given. As is well known, the first edition was produced at Halley's expense. It appeared in July 1687 as one small quarto volume of 500 pages bound in calf and was sold at 10*s*. to 12*s*. a copy. This sold quickly and by 1691 was difficult to obtain. A second edition appeared in 1713, produced with the assistance of Roger Cotes, the young Plumerian professor of astronomy at Cambridge; 750 copies were printed, of which 250 were sent to France and Holland. It sold in England at 15*s*. a copy, and up to 21*s*. bound in calf. Bentley, then master of Trinity College, Cambridge, bore the cost of publication



Jermin Street St James's
7th Jan 1708/9

I have seen some books published by Mr William Jones concerning Algebra, Geometry, Navigation & some other Mathematical Sciences, & find him well skilled in Mathematicks & beleive that in point of knowledge & by his exercise in teaching & experience at Sea he is well qualified for teaching Navigation to the poor boys in the School of the Royall foundation in Christs Hospital. And I am credibly informed that he is also very industrious & understands Latin & ffrench.

Is. Newton

I have long known Mr William Jones, and do humbly subscribe to the opinion of Sr Isaac Newton, that he is very well qualified to teach Navigation in the School aforesaid

Edm: Halley

A testimonial given by Newton, and subscribed by Halley, in favour of William Jones, afterwards a Fellow of the Royal Society, who was applying for a post on the staff of Christ's Hospital. By courtesy of the Royal Society.

Cotes received twelve complimentary copies, but probably he refused all other recompense. A third edition appeared in 1726, but this contained only minor alterations; it was edited by Henry Pemberton, who received £200 from Newton for his work. Pemberton is also reputed to have received £3,000 for his "A View of Sir Isaac Newton's Philosophy", which was published by subscription; the subscribers numbered some 2,400, including peers of the realm, most of the bishops, and other notables including Alexander Pope and Edward Gibbon, a remarkable tribute to the esteem in which Newton was held. Collected editions of Newton's work were published in Lausanne and Geneva in 1744 in three volumes, and in London during 1779–85, though neither is complete. It is to be hoped that steps will be taken to produce a complete edition of the works of Britain's most distinguished natural philosopher.

Sir John Russell, F.R.S.

On September 30, 1943, Sir John Russell will retire from the directorship of the Rothamsted Experimental Station, which he has held since 1912, when he succeeded the late Sir Daniel Hall. During 1907–12 he was Goldsmiths' Company soil chemist at Rothamsted. In these thirty-five years of service Sir John has been associated with striking advances in agricultural science. An early achievement was the evolution of a method—then conveniently described as partial sterilization—for restoring the fertility of rich, but 'sick', soils such as tomato and cucumber beds. A sub-station of Rothamsted was established at Cheshunt, in the centre of the glass-house industry, to deal with this and related problems; its work was so successful that it quickly became an independent research institute. During the War of 1914–18 Sir John was technical adviser to the Food Production Department. Shortly after the War, the agricultural research and advisory organization was greatly expanded by the Government and, in common with other institutes, Rothamsted enlarged its staff and its programme of research to include plant pathology and entomology as well as its traditional subjects of soil science and crop growth. Important scientific advances were made in all of these branches and Sir John attacked the double problem of testing them under varying soil conditions and agricultural systems, and of accelerating their absorption into farm practice. He increased the contacts of Rothamsted with agriculturists and farmers' organizations until the objects and work of the Station became as well known in the countryside as among men of science. Striking proof of this was given in 1934, when the experimental fields were threatened with building developments: a public appeal was issued for funds to purchase the farm, and the amount required, £35,000, was over-subscribed in less than two months.

A further development, sponsored by Sir John, was the extension of Rothamsted's activities to overseas agricultural problems. This work began in 1923 when he was invited to the Sudan to advise on agricultural developments and scientific activities. Since that date he has made extensive visits to the Dominions, India and a number of the Colonies, as well as to many foreign countries, either by direct invitation from their Governments, or as the British Government delegate. He took a leading part in the Imperial Agricultural Research Conference of 1927, as a result of which the Imperial Agricultural Research Bureaux were set up, the one for Soil Science being located at Rothamsted under his direction. In pursuance of his policy of making widely known the scientific and practical results of agricultural research, Sir John has written a number of authoritative books on agricultural science and practice. The best known is "Soil Conditions and Plant Growth", which first appeared in 1912 and is now in its seventh edition. The successive editions contain their own record of the striking advances with which his name is associated. In recent years Sir John has done much to develop the international aspects of agricultural research. But for the War, Rothamsted would have celebrated its centenary in 1943 by an international gathering. This project has been submerged by the urgent war problems and the looming difficulties of post-war agricultural reconstruction in devastated Europe. In these problems Sir John is taking an active part. He serves as adviser to the Russian Branch of the Ministry of Information, and is a member of the Inter-Allied Government Committee on Post-War Requirements.

Bicentenary of Scheele (1742-1786)

The bicentenary of the birth of the Swedish chemist Carl Wilhelm Scheele, whose recently published manuscripts were reviewed in our columns on November 7, falls on December 19. His birthplace was Stralsund, in Pomerania, then a Swedish province, but he was trained as a pharmacist in Gothenburg. Here he remained until the age of twenty-three, studying the works of Stahl, Lémery, Kunckel and Neumann and for ever experimenting. From Gothenburg he went to Malmö, then to Stockholm and Uppsala, where he met Gahn and secured the friendship of Bergmann. At last in 1775, at the age of thirty-three, he was officially appointed apothecary at the little town of Köping on the western shore of Lake Malar. His death took place at Köping on May 19, 1786, when he was only forty-three. Among a crowd of original discoveries those relating to chlorine, manganese and oxygen are the best known. His papers were printed mainly in the *Transactions* of the Royal Academy of Stockholm. Dr. Beddoes translated his "Chemical Essays" in 1786 and a reprint of this was published in 1901. This was reviewed in Nature of November 7, 1901, the reviewer remarking then, "The strict fidelity to experiment, the rare sagacity, the scrupulous and minute observation and the extraordinary experimental skill combine to make Scheele a model for all time. When we add to this the pathos of his early struggles, the simplicity of his blameless life and the nobility of his untimely death, there can be no wonder that Scheele is reckoned a hero among chemists".

University Students and Military Service

In the discussions in the House of Commons on December 9 and 10 on the National Service Bill, 1942, Mr. E. Bevin, Minister of Labour, pointed out that the measure was largely an administrative one to facilitate the calling up of young men of eighteen. The position of prospective university students was discussed by several members of the House. Mr. K. Lindsay remarked that the Bill meant the end of university life in Great Britain during the War, except for a few specialists. Mr. Harvey asked for an assurance that if an undergraduate's work was satisfactory he would be allowed to complete an academic year before being called up. Sir P. Harris said that any advance in education after the War would be impossible without a proper supply of teachers, and hat the proposed call-up would paralyse the whole educational scheme of the country.

Mr. McCorquodale, Parliamentary secretary to the Ministry of Labour, replying to the debate, said that he medical schools would decide on the basis of he first examinations which students would be granted deferment. Scientific students would be ecommended for deferment by the University Joint Recruiting Boards. The Minister of Labour had decided that he could no longer allow boys whose medical grade was sufficiently high to make them liable to serve to go up to the university to take an arts course for one year. This decision would entail he closing down at the end of the summer of the present year's university arts course with the exception of those who were medically unfit for the services. As to the question of mathematics, if a scientific student persuaded the Recruiting Board hat his course was in the interest of the prosecution f the War, he would get facilities for carrying it through. The Bill was read a third time.

Radio Research for the Services

MR. LYTTELTON, Minister of Production, said in the House of Commons on December 9, that in view f the great increase in the importance of wireless communication and radio-location during the War, the Government has set up a Radio Board as the co-ordinating body in regard to inter-Service policy, research, development and production. The Board is in general responsible to the Minister of Production, but where matters of service policy are concerned it takes its instruction from, and is responsible to, the hiefs of Staff Committee. The Minister Resident for Supply in Washington (Colonel Llewellin) acted in is personal capacity as the first chairman of the Board. On his appointment to Washington he was succeeded by the Minister of Aircraft Production, Sir Stafford Cripps, also in his personal capacity. he chairman is assisted by two deputy chairmen, he Parliamentary Secretary to the Ministry of Supply (Mr. Garro-Jones) and Prof. G. P. Thomson. he membership of the Board includes representatives of the Admiralty, War Office, Air Ministry, Ministry of Supply, Ministry of Aircraft Production, and General Post Office, as well as several special non-departmental members. Much of the work of the oard is carried out through two main working ommittees, the Production Planning and Personnel Radio Committee and the Operations and Technical adio Committee, of which Mr. Garro-Jones and Prof. Thomson are respectively chairmen.

New Light Day Bomber for the R.A.F.

RECENT reports of a day raid upon Eindhoven, olland, mention for the first time the use of the Lockheed Ventura I. The R.A.F. type is presumably development of the American machine, originally nown as Lockheed Vega 27. This model is powered by two 2,000 h.p. Pratt and Whitney Wasp 18-ylinder radial engines, and has a speed of 275 miles er hour, with a range of 1,500 miles. It carries a ew of four or five, as necessary, and has armament of two movable and two fixed guns in the nose, a Boulton and Paul gun turret on the top of the body, nd two movable guns underneath. It is probable that the improved version is superior to this in both erformance and armament. The most significant point about the aircraft is that it is a further step towards completing a range of high-performance bombers and fighters that, in total, form a team for heavy day bombing, working upon the theory of smothering the defence when attacking. The Boeing Fortresses operate at great heights, Liberators at a little less, with Venturas, Mustangs and Mosquitoes lower down, even to ground-level. The high speeds and good manœuvrability of these machines make them able to take reasonable evasive action when attacked by anti-aircraft fire, their performance is comparable with British fighters, simplifying the question of their being escorted, and even unescorted their armament and manœuvrability allow them to put up a good defence against enemy attacking fighters.

Recruitment of the Civil Service

THE sixteenth report of the Select Committee on National Expenditure, in a section dealing with the recruitment of the Civil Service, includes some account of the Appointments Department of the Ministry of Labour and National Service, created on March 1, 1942, in which the old Central and Supplementary Registers have been merged, which should be of interest to scientific workers. As a recruiting agency the Ministry's organization now also includes the Temporary Government Service Registers and the Central Register of Aliens, and in regard to the latter, the report recommends that a much more vigorous attempt should be made to keep the Central Register up to date and to find suitable employment for the persons whose names it contains. Reviewing the operation of the Central (Scientific and Technical) Register, the report comments on the relatively slight use made of this Register by industrial firms as compared with Government departments. In regard to engineering appointments, the Committee recommends that academic qualifications should not be allowed to overshadow the less easily assessable but great practical value of men who have graduated through the workshops to management level. It is also recommended that to meet the shortage of persons of managerial capacity, the Ministry of Labour should make a careful search for persons who might be up-graded above the level of their present employment.

The importance is stressed of the Ministry preparing in good time for the difficult post-war task of placing in civil employment the large numbers of men and women demobilized from the Armed Forces, and attention is also directed to the importance, as a means of remedying the shortage of technically qualified recruits in Government departments—and the remark applies equally to industry—of ensuring the most economical use of such persons after appointment. This involves a careful watch on the changing conditions of industry from the point of view of the technical help and supervision needed from the Supply departments. The report also includes a memorandum by Sir James Rae on the professional and technical staffs in Government departments which describes the work of the assessors appointed early last year. This review covers the elimination of functions not essential to the prosecution of the War, the elimination, following if necessary a relaxation of normal peace-time standards, of all work now entrusted to professionally and technically qualified staff which is not absolutely necessary for the discharge of those functions, reduction to a minimum of checking and reference to higher authority, increased collaboration between Departments with the view of avoiding overlapping of functions, a re-organization of the remaining work so as to make the minimum demands on professional qualifications, and to ensure that work not requiring such qualifications is devolved on persons less highly qualified. The report also recommends that delays in the payment of increases of salary either as increments or as the result of promotion should be eliminated, and the immediate investigation of the alleged inadequacy of salaries paid to technical officers. The Committee regards it as fundamental that there should be a reasonable relation between the salaries paid by Government and industrial firms respectively.

Agriculture in Northern Ireland

Addressing a meeting at Ballyclare, Northern Ireland, Mr. J. F. Gordon, the Northern Ireland Minister of Labour, said that during the present year the farmers of Northern Ireland have surpassed all previous records in the production of food. They have increased land cultivation by 100 per cent, and obtained an agricultural turnover during the year of £44,000,000. After feeding the people of Northern Ireland and the troops stationed there the farmers have sent about £10,000,000 worth of food, including 360,000,000 eggs, to swell the larder in Great Britain. The Northern Ireland Ministry of Agriculture has pushed ahead with a scheme of potato processing plant, and it is hoped that nine factories will be completed in time to deal with the 1942 surplus crop, converting it into potato meal for animal feeding and into potato for human consumption.

Depths of the Arctic Ocean

A note on some important Soviet flights in the Arctic is contained in the *Polar Record* of July. In March 1941 Ivan Cherevichni, and four others, flew from Moscow via Archangel, Franz Josef Land and Severnaya Zemlya to their base on Wrangel Island. Thence several flights were made to the north to investigate conditions in the least known area of the Arctic Sea. On the first flight a descent on the pack was made in lat. 81° 2′ N., long. 180° E., and for four days hydrographical observations were made. The ocean depth was 1,447 fm. The next flight was to lat. 78° N., long. 176° 40′ E., where the depth was 1,015 fm., and the third flight was to lat 78° N., long. 170° E., where the depth was 1,878 fm. In the Cherevichni triangle, made by these three stations, the depths appear to be considerably less than the single sounding of Sir Hubert Wilkins in 1927 in lat. 77° 45′ N., long. 175° W., which was 2,830 fm. These discrepancies in depths were not expected in the Arctic Ocean. The physicist in the party found the intermediate layer of warm Atlantic water at all three stations. It will be recalled that this layer, first found by Nansen, was noted by Papanin, of the Soviet drifting polar station, some years ago. It is now fair to assume that it occurs throughout the Arctic basin.

The Couvade

In the recently published September issue of *Folk-Lore*, Mr. L. F. Newman discusses the curious but widespread and ancient custom named 'couvade', which consists in the illness of the husband during his wife's pregnancy, parturition and puerperium. He classifies the theories as to its origin in thre groups according as they are held by (1) the classica school, who follow Apollonius Rhodius, Strabo Plutarch and the other early writers; (2) the historians, who base their views on authors such a Marco Polo, Bacon, Butler and others; and (3) th anthropologists, who are influenced mainly b scientific data and records from the life of the mor primitive peoples. Mr. Newman comes to the con clusion that a number of quite diverse customs hav been grouped together under the name of th 'couvade', and that many are not different types o one definite custom, but are survivals of recorde instances of separate customs and are of multipl origin.

Standardizing Electrical Instruments

In a paper read on December 3 in London befor the Institution of Electrical Engineers, Lieut.-Col. K Edgcumbe dealt with the standardization of industria electrical instruments from the aspects of performanc limits, dimensional limits and certain constructiona features facilitating interchangeability and promotin commercial manufacture, and other minor matte such as preferred terms, definitions, symbols, et Comparisons are made of the standards issued i Great Britain, the United States and Germany an by the International Electrotechnical Commissio suggestions being put forward for the extension c amendment of the pertinent specifications issued b the British Standards Institution, notably *BS*8 *BS*89 and *BS*90.

Announcements

We regret to announce the death of Sir Henr Miers, F.R.S., Waynflete professor of mineralogy i the University of Oxford during 1895–1908, princip of the University of London from 1908 until 191 and vice-chancellor of the University of Manchest and professor of crystallography during 1915–26, c December 10, aged eighty-four.

Dr. G. A. R. Kon has been appointed as the fir occupant of the University of London chair chemistry tenable at the Royal Cancer Hospital (Free which was instituted just before the outbreak of wa Dr. Kon has been a member of the staff of t Imperial College of Science and Technology sin 1925, the title of reader in organic chemistry bei conferred on him in 1935.

It is announced that the estate of Sir Jose Larmor, who died on May 19 (see Nature, June p. 631), amounts to £54,500. He made the followi bequests, among others: £3,000 to St. John's Colleg Cambridge, for annual rewards for undergraduate £3,000 to the Royal Academical Institution, Belfa to supplement scholarships; £3,000 to augme emoluments held by junior members in Northe Ireland of Queen's University, Belfast; £2,000 to t University of Cambridge to provide medical a other assistance to junior members of the Universit £1,000 each to St. John's College, Cambridge, a Magee University College, Londonderry; and £750 ea to Trinity College, Dublin, and the National Universi of Ireland for the benefit of University College, Galwa Subject to other bequests, the residue is to be us for increasing the educational bequests to St. John College, Cambridge, the Royal Belfast Academic Institution, and Queen's University, Belfast.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Discoveries by Accident

PROF. H. R. ROBINSON writes in NATURE of November 21, p. 591: "In November 1895, Röntgen discovered X-rays, largely by accident. Becquerel's discovery of radioactivity in February 1896 was largely a second accident arising out of Röntgen's discovery".

One is tempted to ask, how can it be determined whether a discovery has been made by accident? My colleague in chemistry has provided the following instance of what may legitimately be called an accidental discovery: the fact that mercury acts as a catalyst in the oxidation of naphthalene to phthalic acid by sulphuric acid was revealed by the breaking of a mercury thermometer.

In his "Theory of Light", Preston refers to Arago's discovery in 1811 of the interference of polarized light in the following terms: "Placing by chance a thin plate of mica in the path of a pencil of plane-polarised light and examining it through a doubly refracting prism he observed that both the ordinary and the extraordinary images were richly coloured. . . ." It may have been *by chance* that mica was at hand, but few would call this an accidental discovery because of the associated work and thought of the experimenter.

In the case of Röntgen, no one would gainsay that he was fortunate, lucky perhaps, in having a fluorescent substance on the table, but it may be questioned whether we should call his discovery an accident. According to Glasser, "Röntgen had taken up the work with cathode rays because he had a feeling that there were still many unsolved problems connected with them. . . ." There lay the intention to enter a new field of inquiry, but when a man makes an outstanding discovery in a subject absolutely new to him (as shown by his fifty-eight original papers prior to 1895), it is not surprising to find it attributed to accident, luck or good fortune.

With Becquerel and the discovery of radioactivity the case is rather different, for it was clearly his intention to see whether fluorescent substances emitted anything like X-rays. So the discovery was no accident, though Becquerel had wonderfully good fortune in having at hand a unique collection of uranium compounds handed down by father and grandfather; it was a family discovery.

The subject is a difficult one; for national bias can rarely be eliminated in writing of world events; we become aware in fact of the pitfalls besetting the historian. But I hope that this particular issue may be clarified, for it is a recurrent question in radiological circles: Did Röntgen really discover X-rays, and if so, was it an accident? My usual answers until now have been Yes and No.

SIDNEY RUSS.

Barnato Joel Laboratory,
Middlesex Hospital.

PROF. RUSS has quoted a passage from my *summary* of the Rutherford Memorial Lecture; in the lecture itself I went on to pay a tribute to Röntgen and to Becquerel, emphasizing in particular that there was nothing in their general attack on the problems of X-rays and of radioactivity that could be described as in any way "accidental". My only reason for mentioning at all the element of chance was that in this part of the lecture I was directing attention to the remarkable sequence of largely unrelated events which prepared, at exactly the right time, a field of work for Rutherford and a gateway for his entrance into this field.

The lecture, which occupied about an hour, had to be pruned rather drastically to reduce it to the dimensions appropriate to a printed summary. My unskilful pruning, by divorcing a passage from its context, has clearly left the impression of an opinion of Röntgen's and Becquerel's achievements which I neither held nor wished to convey. I am grateful to Prof. Russ for his letter, and for the opportunity to comment upon it, and so, I hope, to remove all traces of this false impression.

Retarding Effect of Ghost Formation on Absorption from Subcutaneously Implanted Tablets of Hexœstrol

IT has recently been reported[1] that when tablets of synthetic œstrogens are implanted subcutaneously into bovines, the outer or 'cortical' layer of the tablets becomes infiltrated with a structure apparently composed of relatively insoluble protein. The formation of this structure, for which the name 'ghost' was proposed, should not be confused with the phenomenon of encapsulation of the tablet within a sac of fibrous or connective tissue, which was considered by Geist *et al.*[2] to cause a considerable decrease in absorption from tablets implanted into humans. Whatever may be the effect of encapsulation, it was considered likely that ghost formation would retard absorption, and experimental evidence that this is so has now been obtained.

In connexion with investigations on lactation, the absorption (that is, loss in weight) from tablets of pure hexœstrol weighing very nearly 1,000 mgm. each, which were implanted subcutaneously into bovines for periods ranging from 10 to 105 days, has been determined. The tablets were disk-shaped, approximately 14·4 mm. in diameter, 7·8 mm. thick in the centre and 5·7 mm. thick at the edge.

Contrary to the findings of Emmens[3], Forbes[4] and others on rats, the absorption curve, though approximately linear up to 10–15 days (when about 12 per cent of the tablet had been absorbed), bends sharply at this point and thereafter pursues an approximately rectilinear course corresponding to a much-reduced absorption rate. The initial absorption rate was about 9 mgm./day, but by 20 days the rate had fallen to about 1·5 mgm./day. In practically all cases the tablets have been observed to be encapsulated on removal. Though the initial absorption rate is probably proportional to the surface area of the tablet, it is clear that in the present experiments the observed drop in absorption rate was not due to a decrease in tablet area as postulated on theoretical grounds by Emmens[3] and Forbes[4] for their rat experiments, since, after 63 days absorption, for example, the surface area had decreased by only about 8 per cent.

The question now arises as to whether the decrease in absorption is due to encapsulation, ghost formation or, perhaps, both. If ghost formation retards absorption, it would follow that tablets which had been implanted and removed from an animal would, if re-implanted into the same or another host, lose less weight in a given time than new tablets. The results given in the accompanying table, which are typical of others, bear out this expectation, thus showing that ghost formation is an important cause of absorption inhibition.

COMPARISON OF ABSORPTION RATES FROM NEW AND USED TABLETS OF PURE HEXŒSTROL.

No. of Tablet	No. and duration of previous implantations	Initial weight (mgm.)	Approx. surface area (mm.^{2})	Absorption (i.e., loss in weight) in 10 days (mgm.)
C12, cRM	—	1031	584	96·0
C12, cLM	—	1012	590	77·0
C12, cRF	1, (22 days)	862	540	6·5
C12, cLH	1, (22 days)	859	562	7·5
C12, cRH	2, (63 days, and 22 days)	822	539	5·0
C12, cLF	2, (63 days, and 22 days)	808	540	10·5

The tablets were subcutaneously implanted into separate sites in the neck region of a heifer for 10 days.

Moreover, from these and other at present unreported results, it appears that the retardation due to ghost formation is of sufficient magnitude to account for the experimentally observed decrease in absorption rate. This, though it suggests that encapsulation, at least under the conditions of these experiments, has little if any effect on tablet absorption, does not provide absolute proof of this. For it is possible to conceive of a retarding effect due to encapsulation being masked by a bigger effect due to ghost formation. This possibility could be tested if it were possible to prevent ghost formation by some method which had no effect on encapsulation. It may be recalled, however, that Emmens[3] observed encapsulation of tablets implanted into rats, but this did not appear to affect the absorption rate.

It is not yet known whether ghost formation occurs in tablets implanted into small animals but, as pointed out previously[1], it seems likely that the slowing up of absorption due to ghost formation may have to be taken into account in human therapy. These results will be reported in greater detail elsewhere.

Some of the hexœstrol tablets used in this work were provided by Messrs. Boots Pure Drug Co., Ltd., through the kindness of Dr. W. F. Short.

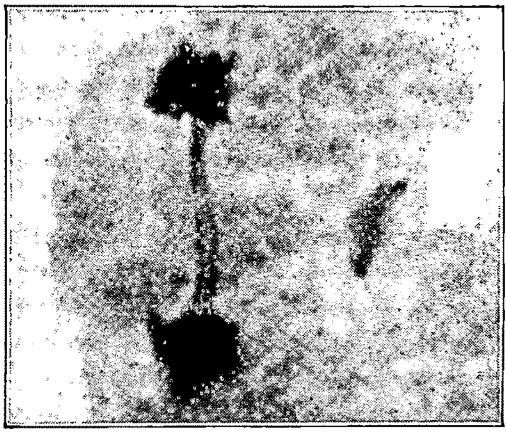
The Telophase Split in Todea

I WAS interested in Dr. Manton's communication with her new and apparently incontrovertible evidence of the telophase split[1]. Her photograph *b* of somatic chromosomes in Todea shows clearly a displaced double strand which has been under a state of tension.



PHOTOGRAPH FROM A PERMANENT ACETO-LACMOID SQUASH[3] OF *Tragopogon pratense* ROOT-TIP SHOWING DOUBLE BRIDGE BETWEEN THE TWO ANAPHASE GROUPS FORMED BY THE DIVISION OF A DICENTRIC CHROMOSOME AND TO ONE SIDE A DOUBLE ACENTRIC CHROMOSOME (× 2000).

The displacement, as Manton points out, is no doubt due in part to squashing, but the stretched double strand is what one always sees with the double chromosome bridges so commonly found in somatic mitosis. For example, in root tips of three-day-old seedlings from two-year-old seeds of *Tragopogon pratense* I have noticed this type of bridge in twenty-two out of seventy-three anaphases. In all cases it was due to the formation of dicentric and acentric chromosomes by interchange in the preceding resting stage. These dicentric chromosomes divide in the three ways described by X-ray experimenters, for example, Koller[2].

The accompanying photograph is of such a dicentric chromosome bridge with its corresponding acentrics from *Tragopogon pratense* for comparison with Manton's photographs. The comparison shows that the so-called telophase split in *Todea* must also be interpreted in this way.

The lower end of the double strand in her Fig. certainly presents the appearance of two centromere which would be expected from the division of a dicentric chromosome. Further, some of the inclusion in this figure are perhaps in reality the acentrics which accompany dicentric bridges and can be of all the expected sizes. The bridges in such anaphase are, of course, always stretched naturally before fixation and not afterwards.

[3] Darlington, C. D., and LaCour, L. F., "The Handling of Chromosomes" (London, 1942).

DR. MANTON's photograph[1], in which she claims to show an "incontrovertible evidence" of the telophase chromosome split, illustrates what can only be a dicentric chromosome. While the long arms form a bridge of the criss-cross type[2], the short arms lie across each other (*b* in photograph). They are the "two distinct separate threads forced widely asunder", and their thickness is the same as that of the long arms (*c* in photograph). The apparent gap between the centromere and the short arm of one chromosome as it is seen in *c* is due to excessive pressure in squashing the preparation.

[4] Manton, I., NATURE, 150, 548 (1942).

[5] Husted, L., *Genetics*, 21, 537 (1936).

IT is perhaps unnecessary for me to inquire into the reasons for the assumption that the evidence from dicentric bridges in Tragopogon is incompatible with the existence of a telophase split in Todea, for the suggestion that the chromosome figured by me was a dicentric is not borne out by anything in the specimen itself. The accompanying diagram, based on my previously published photograph *b*, shows the region referred to. The two distorted chromosomes are labelled *chr* 1 and *chr* 2, *chr* 1 being that under discussion. In it "two distinct and separate threads have been forced widely asunder", the separation starting at a point near the intersection with *chr* 2 which is not otherwise of interest) and continuing to the distal extremity of the chromosome. Near this end both threads experience a sudden bend and the only point of uncertainty is whether or not they also cross over each other at this point.

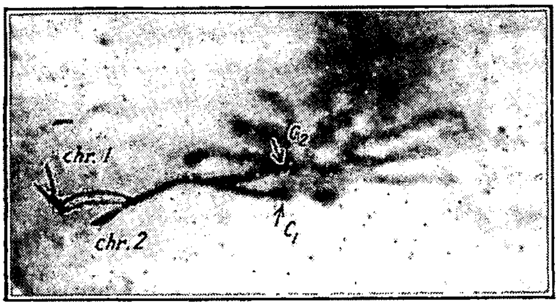

DIAGRAM DRAWN OVER A MATT-SURFACED PRINT OF THE PREVIOUSLY PUBLISHED PHOTOGRAPH *b*. FOR EXPLANATION OF LETTERING SEE TEXT.

The centromeres in both *chr* 1 and *chr* 2, as in all other chromosomes of this plant, are terminal or nearly so and their approximate positions are indicated by arrows and the letters *c* 1 and *c* 2. Owing to the predominance of terminal centromeres the question of short arms, in the form raised by Dr. Koller, does not arise. There are likewise no acentric fragments present, though some cytoplasmic inclusions may perhaps give the illusion of such in the reproduction and be the objects referred to by Dr. Thomas.

The suggestion made by Dr. Koller (if I have understood him aright) that the distal bend is a centromere is discountenanced by comparison with the sister nucleus. The significant part of this was shown in my previous photograph *a*. Had I anticipated that the number and position of centromeres would have been under discussion it would have been easy to show every chromosome in this nucleus by using two or three different focal levels. The level chosen was thought to be sufficient to indicate that the chromosomes were clearly distinguishable and were not disturbed in position. The full haploid complement of chromosomes was present in this nucleus, and therefore if *chr* 1 in the other plate was at any time a bridge it would be necessary to assume it to be a bridge which has broken and been displaced without leaving a trace of its former presence in the sister cell. This appears to me to be highly improbable and has not indeed been claimed.

My opinion that the cell in question was normal is naturally based on a wider knowledge of the material than the one specimen described. I am also acquainted with the appearances caused by dicentrics and fragments in some other organisms, but I have never encountered a case of the kind in the Osmundaceæ. Some positive evidence would therefore be required before one could assume the spontaneous production of chromosomal abnormalities of this kind in a healthy germination of fresh spores from a normal plant.

Further discussion may perhaps be left to the fuller statement which, as indicated in my former note, will be published elsewhere. Additional evidence, which is abundantly to hand, can then more easily be provided.

Catalysts for Sodium Chlorate in Weed Destruction

BATES[1] has shown that vanadium pentoxide acts as a catalyst for sodium chlorate in weed destruction, and suggests the possibility of enhancing the value of this salt as a herbicide by the employment of a catalyst.

Compounds of manganese, cobalt and nickel act as catalysts in many oxidation processes. These metals frequently occur in plant tissues, and the first two are known to play an important part in their life processes, probably on account of their catalytic action. The effect of compounds of these metals on sodium chlorate, and on a proprietary weed-killer, 'Atlacide', which contains sodium chlorate and calcium chloride, has been investigated. The experiments included laboratory and small field tests. A few tests were also carried out with vanadium pentoxide.

The laboratory tests were made on the trailing stems of the Canadian blackberry, the wild dog-rose, and the wild bramble. The cut ends of the stems were placed in tubes each containing 50 c.c. of the solution under test. In most cases ten specimens were tested with each solution. The tests were as follows:

(1) Canadian blackberry stems in solution containing 10 per cent of sodium chlorate, and also with the addition of 0·03 per cent $MnCl_2.4H_2O$* ; 0·03 per cent $MnSO_4.4H_2O$* ; 0·02 per cent $KMnO_4$; 0·04 per cent $CoCl_2.6H_2O$* ; 0·04 per cent $NiSO_4.6H_2O$*.

(2) Canadian blackberry stems in solution containing 5 per cent of sodium chlorate, and also with the addition of 0·015 per cent $MnCl_2.4H_2O$; 0·015 per cent $MnSO_4.4H_2O$; 0·01 per cent $KMnO_4$; 0·02 per cent $CoCl_2.6H_2O$; 0·02 per cent $NiSO_4.6H_2O$; 0·03 per cent $MnCl_2.4H_2O$; 0·03 per cent $MnSO_4.4H_2O$; 0·02 per cent $KMnO_4$; 0·04 per cent $CoCl_2.6H_2O$; 0·04 per cent $NiSO_4.6H_2O$.

(3) Wild bramble stems in solution containing 2·5 per cent of sodium chlorate, and also with the addition of 0·015, 0·03, and 0·06 per cent $MnCl_2.4H_2O$.

(4) Wild bramble stems in solution containing 2·5 per cent of sodium chlorate, and also with the addition of 0·015 and 0·03 per cent $MnCl_2.4H_2O$; and 0·01 per cent V_2O_5.

(5) Wild bramble stems in solution containing 2·5 per cent of sodium chlorate, and also with the addition of 0·06 per cent $MnCl_2.4H_2O$; 0·08 per cent $NiCl_2.6H_2O$; 0·08 per cent $CoSO_4.6H_2O$.

(6) Wild dog-rose stems in solution containing 2·5 per cent of sodium chlorate, and also with the addition of 0·015 and 0·03 per cent $MnCl_2.4H_2O$; and 0·01 per cent V_2O_5.

(7) Wild bramble stems in 1 part 'Atlacide' concentrate to 3 parts water, and also with the addition of 0·03 per cent $MnCl_2.4H_2O$; and 0·04 per cent $CoCl_2.6H_2O$. The diluted concentrate contained 4·825 per cent $NaClO_3$.

(8) Wild bramble stems in a solution containing 0·06 per cent $MnCl_2.4H_2O$; 0·04 per cent $KMnO_4$; 0·08 per cent $CoSO_4.6H_2O$; 0·08 per cent $CoCl_2.6H_2O$; 0·08 per cent $NiSO_4.6H_2O$; 0·08 per cent $NiCl_4.6H_2O$.

* Approximately equal to 0·02 per cent of the anhydrous salt.

A 10 per cent solution of sodium chlorate is stronger than that usually used on this railway, therefore weaker solutions were also employed. The 2·5 per cent solutions were chosen because it was thought that such dilute solutions would not kill the specimens, or would do so very slowly, and that the effect of the catalysts would be more marked. The action was actually somewhat delayed, but all the specimens were killed in 10–18 days, and the action of the catalysts was not appreciably more marked than with the stronger solutions.

Similar results were obtained with all the catalysts. In each case the lethal effect of the chlorate was increased, as shown by the rate at which the specimens died, and the changes which took place in the leaves and stems. The vanadium pentoxide appeared to be somewhat more potent, and to make a more marked difference to the appearance of the plant; the leaves were more blackened and the stems more stained. Little, if any, difference could be observed between the effects of the other catalysts used. Although some effect was observable with 0·01 per cent of catalyst (calculated as anhydrous salt), there was more with 0·02, and still more with 0·04 per cent.

Different strains of the same species showed a marked difference in their powers of resistance. Thus, in test (2), a few stems were still but little affected when all the others were dead. The resistant specimens were all similar to each other in appearance, but differed considerably from the remaining stems. Similar results were obtained with the dog-rose and the wild bramble.

As was to be expected, the solutions of the catalysts alone had no appreciable effect upon the stems. Bates obtained the same result with vanadium pentoxide, and dilute solutions of the other compounds used are known to have a beneficial effect upon plants.

The field tests were carried out on plots each 4 sq. yd. in area, which were chosen so as to be as alike as possible, but considerable differences existed. In each case the weed-killer used was 'Atlacide'. The tests were as follows:

(1) Plots treated with
1 pint 'Atlacide' (1 part concentrate to 3 parts water); 1 pt. containing 0·015 per cent $MnSO_4.4H_2O$; 1 pt. containing 0·03 per cent $MnSO_4.4H_2O$.

(2) Plots treated with
1 pint 'Atlacide' (1 part concentrate to 5 parts water); 1 pt. containing 0·015 per cent $MnSO_4.4H_2O$; 1 pt. containing 0·03 per cent $MnSO_4.4H_2O$; 1 pt. containing 0·04 per cent $CoCl_2.6H_2O$; 1 pt. containing 0·01 per cent V_2O_5.

(3) Plots treated with
1 pint 'Atlacide' (1 part concentrate to 6 parts water; 1 pt. containing 0·03 per cent $MnCl_2.4H_2O$. Two plots were treated with each solution.

(4) Plots treated with
1 pint 'Atlacide' (1 part concentrate to 8 parts water); 1 pt. containing 0·06 per cent $MnCl_2.4H_2O$. Two plots were treated with each solution.

Although the differences between the different plots made close comparison difficult, by comparing the effects on particular species, for example, bindweed (*Convolvulus arvensis*), reliable comparisons could be made. It was evident, especially where weak solutions of 'Atlacide' were used, that the manganese salts were effective in promoting the lethal action of the herbicide. The effects of the other catalysts were not so definite, but this was probably because insufficient tests were carried out with these compounds.

The laboratory and small field tests both show that the salts of manganese, cobalt and nickel, as well as vanadium pentoxide, have an intensifying effect upon the action of sodium chlorate as a weed-killer. It is proposed to carry out larger tests on the track next season, in order to ascertain if the catalytic effect is sufficiently pronounced to justify the use of these materials in practice.

I desire to thank the Chief Engineer, Southern Railway, Mr. G. Ellson, for permission to publish this paper, and Messrs. the Atlas Preservative Company for supplying the sodium chlorate and 'Atlacide'.

Index of X-Ray Diffraction Data

IN response to the demand expressed at the Conference on X-Ray Analysis in Industry held at Cambridge last spring[1], the Institute of Physics has undertaken to supplement the index of X-ray powder patterns published by the American Society for Testing Materials[2]. The purpose of the index is to identify rapidly any substance that will give an X-ray powder photograph[3]. The work is being carried out in co-operation with the interested American bodies—the American Society for X-Ray and Electron Diffraction and the American Society for Testing Materials.

A considerable number of laboratories in Great Britain have furnished lists of substances for which they are able to supply data, and the 'editing' i being done at the Cavendish Laboratory. The purpose of this letter is to ask all people who have powder photographs of substances that might be suitable for inclusion in the supplement to communicate with Dr. A. J. C. Wilson, Cavendish Laboratory, Cambridge. A list of the substances already offered may be obtained from him on request

The X-ray index has already proved to be of considerable industrial importance, and an extensiv supplement will greatly increase its usefulness. It is hoped, therefore, that there will be a wide response to this appeal.

Errors in Mathematical Tables

I AM now trying to consolidate for publication partly in a new American National Research Counci quarterly, and partly in a book entitled "A Computer's Guide to Mathematical Tables", the work that I have done during the past twenty years of compiling lists of errors in mathematical tables. I should be glad to be told of any known errors i tables, or to have references to published lists. New of unpublished tables would also be appreciated.

RESEARCH ITEMS

Starlings and Foot-and-Mouth Disease

There is a body of circumstantial evidence to support the view that the starling, *Sturnus vulgaris* (L.), is concerned with the spread of foot-and-mouth isease in cattle, and this has been reviewed by W. S. Bullough (*Proc. Roy. Soc.*, B, 131; 1942). It s desirable from this, as from more general points of view, that the life-history and habits of this bird hould be studied as fully as possible. The reproductive cycles of the British and Continental races of the starling have been investigated in considerable detail by Dr. Bullough (*Phil. Trans. Roy. Soc.*, B, 231; 1942). The British Isles have their own esident population of starlings, but during autumn and early winter this is augmented by invasions from he Continent. It is possibly significant that Scotland, here foot-and-mouth disease is rare, receives the bulk of its immigrants from Norway, where the disease is almost non-existent. England, on the ontrary, where the disease is common, receives its nflux from north Central Europe, where the disease prevalent, and many unexplained outbreaks start n the late autumn after the Continental migration f starlings has set in. The residents and migrants onstitute two different races which can be distinguished in both sexes by minor differences, but there also a difference in their reproductive cycles. The exual cycle of the British race commences earlier nd proceeds more rapidly, with the consequent arlier and quicker development of the breeding haracters. British starlings pair in autumn but the ontinental ones do not do so until they return to heir nesting places in March, and thus there is no nterbreeding between the two races (see also Nature, une 20, p. 683)

Great Barrier Reef Bores

Vol. 5 of the Reports of the Great Barrier Reef ommittee (dated April 30, 1942, and issued from risbane) has been drawn up by H. C. Richards and orothy Hill. They describe the detailed examination f two bores taken at Michaelmas Cay, 23 miles orth-north-east of Cairns in 1926 and at the southern nd of Heron Island in 1937. General accounts have ready been published. The sites were 700 miles part and the bores were put down to a depth of 0 ft. and 732 ft. respectively. The results of these oring operations are remarkably alike. The occur-ence of none but species of corals and molluscs which are found living in the same region to-day ndicates that the bores passed through materials eposited entirely during recent times. It is shown hat a subsidence of about 100 fathoms almost ertainly must have occurred, and this subsidence nd the deposition must have been rapid. The most mportant characters the bores have in common are he great thickness of reef materials in the upper part of each, the occurrence of reef corals through he top 506 ft. in the Heron Island bore and the top 76 ft. of the Michaelmas Cay bore, the occurrence of uartz-foraminiferal sands below the reef rock and he absence of a basement even at 732 ft. The bsence of dolomitization, the presence of two ragonite zones and the lack of sufficient cohesion n the material to yield cores comparable with those btained at Funafuti and the Bahamas show that milar conditions have affected the materials since heir deposition.

Vascular System of *Xenopus laevis*

While *Xenopus lævis* is the common form of Anuran amphibian studied in courses of biology in South Africa, only very inadequate and incomplete accounts of its blood vascular system were available until Naomi Millard's account appeared (*Trans. Roy. Soc. South Africa*, 28; 1941). This is a concise description of the arteries and veins of this species, fully illustrated by diagrams that are all the more clear since the vessels are shown in colour. Xenopus is an interesting species as it is a member of the Aglossa, whereas the previous accounts of the blood vessels of Anurans have been based on members of the Phaneroglossa. Investigations into other anatomical features of the group have suggested that it occupies a primitive position in the Anura. While the main plan of the vessels is undoubtedly Anuran, it is interesting to note that in certain details, particularly the veins of the hind limb and the abdominal veins, relationships are present that suggest conditions otherwise encountered in the Urodela, for example, *Salamandra salamandra*. The author concludes that these and other similarities do not imply close affinity but are rather due to both animals being neotenic. Some of the other peculiarities and abnormalities encountered will probably find explanations when the developmental history of the system is worked out. The abnormalities, a number of which are described, appear to occur in a greater percentage of the specimens than they do in the Ranidæ.

Effect of Colchicine

J. G. Hawkes (*J. Genetics*, 44, 11–22; 1942) has shown that colchicine only exerts its effect on those mitotic stages where a spindle mechanism is present. The centromeres of chromosomes treated with colchicine do not divide until the resting stage which follows the treatment, while the succeeding metaphase is followed by the formation of a lobed restitution nucleus. The orientation of the spindle in the root tip is distorted by colchicine, and this gives rise to the production of a swollen root tip. Absence of polarity of colchicine-treated cell divisions is a cause of the noticeable swellings of the roots. The duration of a cell-division cycle after colchicine is 33 hours in *Allium cepa*, which is about twice as long as a normal cell division in comparable circumstances.

Intergeneric Hybrids of Saccharum

Several hybrids between *S. officinarum* and *Narenga porphyrocoma*, made by C. A. Barber in 1913, have been analysed by E. K. Janaki-Ammal (*J. Genetics*, 44, 23–32; 1942). The parents have $2n = 80$ and $2n = 30$ chromosomes respectively. The hybrids have $2n = 55$ chromosomes. Chromosomes in the hybrid show autosyndesis and associate as quadrivalents, trivalents and bivalents. This may be the cause of male and female sterility in the hybrids, which would appear to be similar to the hybrid form 'Hitam Rokham' which is found wild.

Origin of Tetraploid Shoots in *Brassica oleracea*

H. W. Howard (*J. Genetics*, 44, 1–9; 1942) has analysed the origin of tetraploid shoots in *Brassica oleracea* after decapitation. New meristems arise from the cells of the callus, which were produced by large vacuolated cells. No increase in the proportion of the tetraploid shoots has been induced by treatment with hetero-auxin. The author considers it probable that tetraploid meristems arise from cells of the stem which contained diplo-chromosomes before injury, and that decapitation as such did not induce chromosome doubling.

Structure of Lead Chromate

The work of Brill (*Z. Krist.*, 77, 506 ; 1931) showed that lead chromate (crocoite) is monoclinic, that there are four $PbCrO_4$ molecules per unit cell, and that the probable space group is $C^{5}_{2h}-P2_1/n$. S. B. Brody (*J. Chem. Phys.*, 10, 650 ; 1942) has confirmed these data, which indicate that lead chromate cannot be classified with any other oxy-acid substance so far investigated. Simple rotation and Weissenberg equi-inclination X-ray photographs were taken about the *b* and *c* axes, using unfiltered copper radiation. The intensities were carefully corrected for polarization and absorption. Parameters for the lead and chromium atoms have been obtained but the electron density maps were insufficiently accurate to locate the oxygen parameters. There is evidence, however, that the structure is fairly close packed and that the co-ordination number of oxygen atoms about lead is probably 8 or more. It is concluded that the mechanism of photo-conductivity and photo-blackening in lead chromate must take place by migration of ions by means of holes due to lattice defects.

Counting Free Alkyl Radicals

An interesting method, whereby free alkyl radicals produced by photolysis can be counted, has just been published by M. H. Feldman, J. E. Ricci, and M. Burton (*J. Chem. Phys.*, 10, 618 ; 1942). Inside a reaction tube, long, heavy mirrors of lead are deposited and the lead is then carried from this tube by free alkyl radicals (Paneth method). The lead alkyl is brought in contact with a mixture of bromine and carbon tetrachloride whereby it is converted to lead bromide. Volatile substances are carefully distilled off and the lead determined by the dithizone method. Thus, assuming that all the alkyl radicals are 'mirror-active' and that only PbR_4 is formed, the number of radicals can be estimated. The half-life of the methyl radicals produced in the photolysis of acetone by 2537 A. mercury radiation at 45° is $1{\cdot}1 \times 10^{-2}$ sec. and at 100°, 8×10^{-3} sec. This difference appears to be due to the instability of free acetyl radicals produced according to $(CH_3)_2CO + h\nu \rightarrow CH_3 + CH_3CO$ and decomposing to CH_3 and CO. The concentration of free methyl radicals flowing past the irradiated portion of the tube has been computed to be approximately $1{\cdot}7 \times 10^{-12}$ mols per c.c. when $2{\cdot}7 \times 10^5$ c.c. of gas passes this point in 5 minutes. The number of mols of methyl picked up during that time at that point is $4{\cdot}6 \times 10^{-7}$.

Differential Electronic Stabilizer for Alternating Voltages

A paper read recently in London by Arvon Glynne before the Institution of Electrical Engineers describes the construction of a differential electronic stabilizer, which has been designed to provide a supply unaffected by fluctuations in the mains voltage, for testing A.C. instruments. A simple lamp stabilizer is also described. A bridge consisting of two lamps and two resistors is an essential part of the apparatus, for which the mathematical theory is developed, and experimental evidence of the accuracy of the theory is given. Applications of the differential stabilizer to the testing of D.C. and A.C. indicating instruments and of light- and heavy-current integra ing meters are described, and an account is given the use of stabilized voltages for A.C. potentiometr Both stabilizers have been in constant use for son time for standardizing instruments, and have prove to be very reliable and to require very little attentio When checking integrating meters, one observer now able to perform all duties, and it is believed th the precision of the measurements has been materiall increased. A single observer is now able to check a number of indicating instruments, as he is assure that the readings will not alter as he passes from o to the other. With the unsteady supplies previousl available, the A.C. potentiometer has been regarde as a troublesome and unreliable instrument unsui able for serious work, but it has now taken its prop place as a precision instrument. The stabilizer h been developed principally for use with single-pha supplies, but it can also be used with equal success f checking polyphase instruments.

Calculation of Precession

Star catalogues are now reduced to standa equinoxes at intervals of twenty-five years, an tables specially relating to the two epochs are com piled for the purpose, or more rigorous formulæ spherical trigonometry are used. In the case of sta of high declination, where a formal accuracy of least $0{\cdot}01^s$ in R.A. is desirable, it is often necessa to utilize the rigorous method. In these circum stances, where the spherical triangle involved small, Legendre's theorem can be applied, and t formulæ used produce errors which *decrease* as t pole is approached. This theorem states that cases where the sides of a spherical triangle are sma compared with the radius of the sphere, the spheric triangle may be replaced by a plane triangle, th sides of which are of the same length as the arcs the spherical triangle, but each angle is less by o third of the spherical excess than the correspondi angle of the spherical triangle. This principle h been applied in geodetic operations but has not be used in astronomical computations. D. H. Sadle superintendent of H.M. Nautical Almanac Office, h now shown (*Mon. Not. Roy. Astro. Soc.*, **102**, 4) ho the principle leads to some simple formulæ whi can be used for the reduction of star positions fro one equinox to another. They possess the gre advantage that accuracy of computation increas as the pole is approached, and they are easier to u than the ordinary rigorous formulæ employed spherical trigonometry.

Galactic Clusters in Relation to the Galaxy

As a result of his investigations, George Alt concludes that the observed distribution of clust numbers is due to a true eccentric displacement the sun in a real cluster system which is not mere a selection from a general random distribution (*Mo Not. Roy. Astro. Soc.*, **102**, 4). The centre of th cluster system is about 250° longitude. The asy metrical distribution of absorption conditions longitude as well as the presence of the so-call 'galactic windows' indicate that most of the absor tion is due to irregular clouds which accumula towards the galactic centre in the direction of 35 galactic longitude. In this direction the absorpti coefficient increases by about 5 per cent per ki parsec, but in any other direction the change smaller.

QUALIFICATIONS OF THE SOCIAL PSYCHOLOGIST

PROF. T. H. PEAR criticizes severely but kindly in an interesting article those who profess social psychology*. The social psychologist too frequently fails to qualify for his job by obeying the old injunction of 'know thyself'. Also in his attitude towards his subject he is too remote from the hurly-burly of everyday life, in fact, too 'pure'. Some sciences can be pursued advantageously with little contact with, or relation to, humanity, but such is not the case with social psychology. On the other hand, he must resist the temptation to slip into the attitude of the novelist, artist or even comfort lover.

The direction of any science is determined, to an extent not usually admitted, by the inborn and acquired mental peculiarities of its leaders and by their social and economic status. Most social psychology has been produced in Great Britain by members of the middle class, and they have too often been unaware of this limiting factor. Examples of this attitude of mind have sometimes been thrown into relief during the War. For example, in discussing fuel saving, some people who had never known what it was not to be able to have a bath when they wanted one, suggested a nation-wide campaign urging people not to have more than two hot baths a week, in blind ignorance that there were numerous bathless houses.

Leaders of thought brought up in a particular environment are apt to think that certain subjects are important or trivial, popular or dull, in general, though a different culture group might hold quite different views. A social psychologist must not be 'tuned in' merely to those expressions of social life which the conventions of his social milieu regard as important. For example, the subjects of speaking and conversing are generally neglected. That such problems as standard English, the prejudices for and against certain kinds of dialect, are social, is unrealized. To delve into them would break a taboo all the stronger because in most people it is unconscious.

Therefore, before entering upon any research in social psychology the investigator should know his own social background, and the ways in which it may have given him special prejudices.

Industrial research is not a bad training in this respect. If the investigator is in one factory for a considerable time, he will have ample opportunities for finding out, incidentally to his main work, what people do think, or say they think, about the topics that are of current interest. A point of importance in this connexion is that much of what is said has to be translated or interpreted. Some students of public opinion are apt to overlook that, in Great Britain at least, to express an opinion is not synonymous with being prepared to act upon it. Much gossip and expression of opinion is of the nature of a probe to see what other people are like or think.

The somewhat humdrum task of finding out how we ourselves behave in particular circumstances, and how others do, is vitally necessary for the development of social psychology.

Prof. Pear thinks that too many men of science believe that those who are not trying to establish general laws are wasting time, even when there may be a serious shortage of facts in the particular subject. Even books about the human mind are often of this kind and suffer from a paucity of examples. Social psychologists have no right to neglect the observation, recording and classification of concrete data. Their scientific training would be shown in the way they used their data. In short, they must not spend their days in the study, but frequent the market-place, and know their own blind spots, mental and social.

* The Social Status of the Psychologist and its Effect upon his Work. By Prof. T. H. Pear, *Sociol. Rev.*, 34 (Jan-April, 1942).

SCATTERING OF LIGHT

THE interest which for many years now has been displayed by Indian workers on phenomena of light scattering has produced a large volume of valuable observations and many important and far-reaching results. While, since 1928, investigations have been predominantly concerned with different aspects of the Raman effect, other branches of light scattering have received attention. Many individual papers have appeared, but periodically a symposium of papers is published. These are most helpful in weaving together the various topics. The one under review* on "Fluorescence, Light Scattering, and the Raman Effect" worthily follows the traditions created by previous symposia and maintains the same high standard.

The symposium opens with two papers by P. G. N. Nayar on the absorption and scattering of light in diamonds. His earlier work had shown that both in fluorescence and absorption the entire spectrum is closely related to the 4152 A. band. Examination of these spectra at liquid-air temperature has now revealed the existence of a considerable number of discrete lines in the spectra with frequency shifts varying from 178 to 1330 cm.$^{-1}$ and, further, has shown the perfect mirror-image symmetry in the shifts and in the intensities of these lines with respect to the 4152 A. line. These data enable the author to derive the full lattice spectrum of the diamond, and the discrete character of this spectrum postulates that atomic oscillations in a simple crystalline solid are of a different nature from those of an elastic solid. Further, the derived spectrum contains practically all the known Raman and infra-red frequencies and indicates that the spectrum is richer in frequencies than had been supposed. The investigation of the ultra-violet absorption in the temperature range 85°–300° has demonstrated that the 4152 A. line is a doublet, that between 3015 and 3447 A. there are some twenty-five distinct lines, that below 3000 A. there is an unresolved group, and that the influence of temperature on all lines is of the same order of magnitude. Investigation of the changes in frequency, intensity, and polarization of the 1332 cm.$^{-1}$ Raman line with crystal setting and angle of scattering show that the frequency and intensity are unaltered. The depolarization factor is 1, not 2 as obtained theoretically. One other interesting point emerges in the constancy of the intensity and frequency of the 1332 cm.$^{-1}$ line in diamonds exhibiting widely different fluorescence and absorption properties.

B. S. Satyanarayana discusses the fluorescence of uranyl compounds. In the solid state the fluorescence spectrum consists of eight discrete bands having a wave number separation of approximately 860 cm.$^{-1}$. The Raman spectrum of the uranyl $UO_2{}^{++}$ ion con-

---

Proc. Indian Acad. Sci., *A*, 15, 293-416 (1942).

sists of three displacements of 211, 865, and 909 cm.$^{-1}$. It is concluded from an analysis of the Raman data that the ion has a symmetrical, bent structure.

More than workers in other countries, Indian physicists have directed attention to the interesting changes in the Raman spectra of crystals on account of different crystal settings, and of the influences of the directions of the incident and scattered radiation. T. M. K. Nedungadi has extended our knowledge on this topic by an exhaustive investigation of the Raman effect in a single crystal of naphthalene. The spectrograms obtained for various settings of the crystal with respect to the directions of the incident radiation and the line of observation and with various directions of vibration in the incident and scattered radiation are reproduced. Experimental data confirm predictions of group theory that six low-frequency lattice oscillations exist in three pairs of close doublets: 38, 47; 72, 78; and 107, 121 cm.$^{-1}$. The higher member of each pair arises from oscillations symmetrical to the elements of symmetry of the monoclinic lattice, whereas the lower members of the pairs are due to antisymmetrical oscillations. On frequency and intensity considerations these pairs of lines correspond roughly with rotational oscillations of the molecule. Theoretically, naphthalene should possess twenty-four normal modes of vibration and these have been identified. Polarization data have shown that some of the internal oscillations, particularly 512 and 1576 cm.$^{-1}$, split up into symmetric and antisymmetric components; this is interpreted as showing that polarization data are controlled, as are lattice oscillations, by symmetry properties.

Work continues on determination of the Raman frequencies and their intensities and polarization characteristics and on deducing the characteristic Raman frequencies of chemical groups and linkages. Contributions in this direction are made by Dr. C. S. Venkateswaran and N. S. Pandya with data on aniline, diethyl sulphide, and two binary liquid mixtures. The binary mixtures investigated—*cyclo*hexane-aniline and *iso*-propyl alcohol-water—possess a critical solution temperature and, from changes in the position and intensity of five lines of the second mixture, it is concluded that at the critical solution temperature only monomeric molecules of *iso*-propyl alcohol exist. This is an interesting new departure in Raman spectral investigations, and shows that the directions in which the methods of Raman spectra can be applied to the investigation of chemical problems are, indeed, manifold.

The remaining papers of the symposium deal with the scattering of light in gases, in mobile and viscous liquids, in glasses, in alcohols, and in emulsions. The light scattered in a transverse horizontal direction by dilute emulsions is usually elliptically polarized, whereas the scattered light from concentrated emulsions is highly depolarized. In a large variety of liquids hypersonic velocities have been determined and compared with acoustic velocities. K. S. Bai has examined existing theories of light transversely scattered by liquids and has derived thermodynamically a general expression for the intensity.

The contents of the papers constituting the symposium will prove extremely valuable not only to all directly concerned with this field of scientific inquiry, but also to a wide circle of chemists and physicists interested in the applications of these methods to a variety of problems.

W. Rogie Angus.

THE LOCUST PLAGUE

By Dr. A. D. Imms, F.R.S.

One of the oldest of all agricultural problems is that of locust invasions. References to such plagues are frequent in the texts of the ancient Egyptians, Greeks, Chinese and Hebrews—the oldest dates back to more than 2000 years B.C. These depredations are not confined to a few countries, although outbreaks regularly appear in individual lands only to devastate many distant territories. It cannot be emphasized too strongly that much of the failure to control these plagues has been due to isolationist policy adopted by those countries directly affected.

This feature was stressed by Dr. B. P. Uvarov in a lecture delivered by him before the Dominions and Colonies Section of the Royal Society of Arts on December 15. As Dr. Uvarov pointed out, history provides examples of great efforts to control locusts in Algeria, Argentina, South Africa, etc., with only temporary results simply because the problem is insoluble within the confines of a single country. He mentions the example of swarms of the desert locust, bred in India, that usually migrate to Persia and Arabia and their descendants proceed to spread over Egypt, Palestine and East Africa.

It is now generally agreed among investigators, and the more enlightened administrators of locust control methods, that international co-operation affords the only sure method leading to the ultimate and permanent solution of the problem. Sporadic attempts to approach some measure of international co-operation have not been lacking, but no practical effect resulted owing to failure to take scientifically planned concerted measures. In 1928 a severe outbreak of the desert locust was the moving factor in the British Government deciding to take steps that might lead to a solution of the causes of the periodical swarming of locusts and the resulting depredations. A Locust Sub-Committee of the Committee of Civil Research (later transformed into the Committee on Locust Control of the Economic Advisory Council) was formed. The actual work was undertaken by a special research unit under the supervision of Sir Guy Marshall and under the technical supervision of Dr. B. P. Uvarov. The history of this important venture and the results so far obtained were dealt with in the lecture referred to. In a few words it may be said that this purely British organization soon attracted attention in other lands.

The first International Locust Conference at Rome in 1930 requested the British organization to act as the centre of anti-locust research. Concerted investigations by parties of British, Belgian, South African, Egyptian and Indian experts have gradually led towards a fundamental understanding of the whole problem. After eight years of intensive work it has become possible to formulate a policy that aims directly at a radical solution of the difficulties. The investigations referred to have yielded abundant data showing that the periodicity of locust outbreaks is closely connected with transformation of these insects from the harmless solitary phase into the dangerous migratory, gregarious one. The transformation can happen only in certain localized areas with special conditions of climate and vegetation which differ for different locust species. It is in these outbreak areas that the first swarms are formed. The important discovery that great locust invasions have such restricted beginnings has vital implications. It means that once these original outbreak areas are known they can be kept under proper observation, and any tendency towards the formation of incipient swarms can be dealt with before such swarms can spread and cause widespread devastation. It cannot be too strongly emphasized that Dr. Uvarov himself is the guiding agent in all this international locust policy, as it was his original phase theory that provided the scientific basis for the new outlook on the problem as a whole.

STUMP PRODUCTION IN MADRAS TEAK NURSERIES

WHAT has come to be known as stump planting, that is, the use of root and shoot cuttings, has been long known in India, some of the earliest experiments made in this direction having been successfully attempted with the sissu (*Dalburgia Sissoo*) in the irrigated plantations in the Punjab. In *Indian Forest Records*, 4, No. 5, 1941 (Manager, Government of India Press, New Delhi, 1942), A. L. Griffith says that the planting of stumps in Madras displaced direct dibbling of seed and transplanting, as had been done up to that time. In the early days of stump planting in the presidency a number of experimental investigations were undertaken and continued over some years. Mr. Griffiths summarizes the results in the following tentative conclusions for work in a general West coasts type of climate:

(*a*) The best density of sowing to use is that of 1/8 lb. to 1/5 lb. of teak seed per square foot of nursery bed, and to do no pricking out of seedlings at all. This is most economical in quantity of seed and results in a high proportion of the stumps produced being of the best size for planting at 1 year old (that is, 0·4–0·8 in. diameter). (*b*) Thus, one standard 40 ft. × 4 ft. nursery bed sown evenly with 20–30 lb. of seed *on the average* produces enough well-shaped stumps of usable size to plant 1 acre of plantation at a 6 ft. × 6 ft. espacement and also leaves in reserve for casualty replacement. (*c*) Poor seed years have to be guarded against, and at the end of the first year either the undersized plants can be left in the bed and these together with germination from seed still dormant will produce a full bed of good-sized plants at the end of the second year, or the undersized plants can be pulled out with the bigger ones, stumped, and put back into a reformed nursery bed. These plants at the end of the second year will give a high proportion of well-shaped, good-sized stumps which are in no way inferior to fresh, good-sized one year old stumps. (*d*) Although teak stumps store well, and travel well, a large central permanent nursery for the production of stumps for an extensive area does not appear advisable, as in a few years stump production falls off seriously in most localities as a result of continued cropping, and this falling off was not prevented by manuring with artificial manure, or by fallowing, or by growing a green manure crop of sunn hemp in alternate years. In addition, pest attack by cockchafer and white ants may be serious in a permanent nursery and occurred in two out of the five years of experiment.

The conclusion arrived at between the permanent and the temporary or flying nursery is most important and of high interest,

ANALYSIS OF ELECTRICAL CONTACT EFFECTS

IN a paper entitled "Contact Non-Linearity, with reference to the Metal Rectifier and the Carborundum Ceramic Non-Linear Resistor" (*J. Inst. Elec. Eng.*, 89, Pt. 1, No. 23; November 1942), A. Fairweather gives an account of an experimental analysis designed to correlate and formulate the behaviour of various structures possessing contact non-linearity. New data are presented concerning representative contact combinations such as various carborundum combinations, the carborundum ceramic non-linear resistor, the cuprous oxide and selenium rectifiers, and the diamond. Measurements have been made of the variation of the characteristic parameters, resistance and capacitance, with each of the four significant variables—current, mechanical pressure, thickness of semi-conductor and temperature. The ranges of current and voltage far exceed those which have been employed hitherto. Examination of the results obtained leads to various conclusions regarding the mechanism of contact non-linearity, but not, however, in conflict with the familiar 'barrier layer' hypothesis, which is fully supported by the work described.

It would seem that three clearly defined regions of operation hold for conduction in both directions through a contact possessing contact non-linearity. For 'small' voltages and for 'large' voltages conduction is ohmic: for 'medium' voltages, which are largely those of interest, conduction is non-linear, and obeys a simple empirical equation of the form $V = Ki^n$, where n depends mainly on the materials, and K on the dimensions, of the contact combination. This type of law might hold for all contact combinations, and its importance is such as to warrant the development of a theory of circuits containing a non-linear resistor having such a characteristic. Since the contact is never likely to be perfect, the current will be concentrated at a number of spots which may be regarded as imperfections in the boundary. The 'small' voltage ohmic resistance is thus identified as a constant resistance arising from spreading current paths associated with these spots. The 'large' voltage ohmic resistance is due to the resistance of the bulk electrodes, which becomes all-important when the boundary resistance has become sufficiently small. The 'medium' voltage non-linear resistance results from conduction across the nominally insulating portion of the boundary.

The simple gap picture of the boundary seems to have been discarded prematurely. In the case of the cuprous oxide rectifier, where it is generally supposed that the boundary layer consists of highly insulating, oxygen-free cuprous oxide, such gaps might result from intercrystalline or crystalline cracking at the boundary, arising during cooling from the high temperature of preparation, and this picture is in closer agreement with the results of experiment. The importance of two much neglected aspects of contact non-linearity are stressed: first, the capacitance parameter, as a possible source of information regarding the insulating portions of the boundary layer, and secondly, the necessity for using structures which are previously unstressed mechanically, for detailed study.

Carborundum, cuprous oxide, and selenium are all shown to be ohmic conductors, in opposition to the views of some workers. The tests on contacts between diamonds—a very high-resistance crystalline material —have suggested the probable existence of an apparently anomalous effect, in that the contact resistance in the non-linear region increases with increasing voltage. This is thought to be related to the familiar resistance maximum occurring in the reverse direction with the metal rectifier.

FORTHCOMING EVENTS

Sunday, December 20

Workers' Educational Association (Glasgow Branch), Association of Scientific Workers (Scottish Area), Workers' Educational Trade Union Committee (Scottish Area), and the Educational Institute of Scotland (Glasgow Association) (in the Glasgow and West Scotland Commercial College, Pitt Street, Glasgow, C.2).—Joint Conference on "Science and the Struggle for Freedom". At 10.30 a.m.—Prof. H. Levy, Prof. V. Gordon Childe and Dr. C. Ockrent: "Science in the Struggle against Fascism"; at 2.30 p.m.—Dr. Martin Ruheman, Dr. F. Haldane and Mr. C. R. Wason: "Science in the Soviet Union".

Monday, December 21

Royal Geographical Society (at Kensington Gore, London, S.W.7), at 5 p.m.—Mount Everest Films from the Expeditions of 1922 and 1933 and the Flight of 1933.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Teacher (man or woman) of Mathematics in the Technical Day School—The Clerk to the Governors, South-West Essex Technical College and School of Art, Forest Road, Walthamstow, London, E.17 (December 23).

Assistant Mistress to teach Biology and some subsidiary Chemistry and Physics—The Clerk to the Governors, South-East Essex Technical College, Longbridge Road, Dagenham (December 28).

Assistant Lecturer and Demonstrator in Botany—The Secretary, West of Scotland Agricultural College, 6 Blythswood Square, Glasgow (December 28).

Woman Psychologist for service at the Child Guidance Clinic—The Chief Education Officer, Education Office, Council House, Margaret Street, Birmingham 3 (January 9).

Regius Professor of Geology at Edinburgh University—The Private Secretary, Scottish Office, Fielden House, 10 Great College Street, London, S.W.1 (January 11).

Graduate fully qualified to teach Physics—The Headmaster, Royal Liberty School, Romford.

ANGLO-AMERICAN COLLABORATION IN AFRICA

AN admirable study of Africa and the Atlantic Charter from what might well be called the point of view of the United Nations has been issued by the Committee on Africa, the War and Peace Aims*. Its main purpose is to help to focus public opinion on the constructive treatment of African problems, and in presenting a document suitable as a basis for study in various groups in the United States, the Committee has also provided one equally fitted to promote in Great Britain the long neglected cause of education in imperial history. Attention is indeed concentrated on European-African relations, and the differences in the policies of different European Governments are recognized, as well as those existing between areas of large white permanent settlement such as Southern Rhodesia, Angola and South-West Africa, and to a lesser extent Kenya, and those like Nigeria, the Gold Coast and West Africa, where there is no such group. The solution of African problems is a complicated one, and the presence of those qualified to deal with African problems will be essential at the peace conference if that settlement is to implement a constructive attack on the problems of African poverty and retarded development with the definite object of fitting the African for self-government.

From the major findings of this Committee there will be little dissent. The need for intelligent study of Africa, its position as a great undeveloped area with minerals, agricultural land, water-power and other natural resources steadily decreasing in value through careless or reckless use or exploitation, the differing policies of the various European powers in control, the potentialities of the indigenous peoples—with these Lord Hailey's larger survey has already done something to familiarize opinion. There is generous recognition in this report of the integrity and personal character of the British Colonial service, of the pursuit of progressive social welfare ideals, and of the progress made in most parts of Africa under the influence of the mandate idea of trusteeship in dealing with the problems of native rights and welfare. It should not require the stimulus of the American landings in Liberia and in Northern Africa to accord equally full recognition of America's missionary, financial, educational, scientific and other interests in Africa, all increased by the existence in the United States of the largest educated Negro population in the world.

The recommendations of the Committee are equally in harmony with the policy of development to which Great Britain has committed itself in the establishment of the Colonial Development Fund, and still more that new conception of wardship which Lord Hailey has emphasized as needed in place of the older conception of trusteeship, with its implication of status rather than development. They are in fact largely anticipated by the proposals of a P E P broadsheet issued earlier in the year.

---

* The Atlantic Charter and Africa from an American Standpoint: a Study by the Committee on Africa, the War, and Peace Aims. Pp. xi+164. (New York: The African Bureau; London: Edinburgh House Press, 1942.) 75 cents; 4s.

The Africa Committee urges that the lessons of recent military defeats in Malaya, Java and Burma emphasize the importance of prompt steps to give Colonial peoples a larger and more responsible share in the government of their country; otherwise measures to meet their legitimate aspirations may be "too little and too late". The close analysis of each of the eight points of the Atlantic Charter leads to the recommendation that each point should be applied to Africa in keeping with the broad humanitarian and democratic principles enunciated. The goal of ultimate self-government should be accepted for all the Colonies, and every effort made to secure the best public opinion of the African population when changes in government control or policy are contemplated, to provide adequate local representation in the machinery of government either in the legislative council or by tribal councils, and to open positions in the Civil Service in every Colony of the country to Africans.

Like Lord Hailey, the Committee endorses the conception of guardianship rather than of trusteeship, with its implication of temporary rather than permanent relationship, but otherwise it strongly supports the application of the mandate ideal both in those territories controlled by European powers and in the independent African States. In regard to social and economic relations, it stresses the importance of the elimination of all forms of racial discrimination, of special attention to the fundamental problems of land and agricultural development, the prevention of exploitation and deterioration of natural resources, and an educational policy related to the needs of the people and calculated to provide the leadership required in all branches of life. The exceptionally serious health problems of Africa are also recognized as requiring special attention.

There can be no doubt as to the sympathy and understanding with which African problems are viewed by those responsible for this report, and American co-operation in so cordial and generous a spirit should be sure of a warm welcome. America's own mistakes in dealing with racial problems are frankly recognized, and this call, addressed primarily to the people of the United States for a keener interest in African affairs and for closer relations with Africa, will be strengthened by the stimulus which the march of events has given.

Whether or not the Government of the United States is likely to consider the final recommendation of this Committee regarding the establishment of a separate Division, staffed mainly with personnel with African experience, to deal with African-American affairs, in place of the old system in which such matters were handled by the Near East Division or the West European Division, a Colonial commission working through such institutions as the regional development agencies and international public concerns suggested in the Planning broadsheet and discussed recently by Dr. Julian Huxley in the *Political Quarterly* seem to offer an effective channel for American co-operation. There is no gap between progressive thought in Great Britain and that in the United States on Colonial affairs—indeed, if anything the more immediately practical and constructive proposals have come from groups in Great Britain, as might be expected from the somewhat closer contact with African affairs. What is important is that there should be goodwill and understanding on both sides, and the determination to work together in support of the great ideals which the two Anglo-Saxon democracies share.

This report will encourage that understanding in the United States, and also the sympathetic approach to African problems which takes account not merely of the ideally desirable but also of the practicable. The Committee, it will be noted, does not go so far as to prescribe a time-table as does Mr. Wilkie, and the need for flexibility is recognized. Such moderation is all the more calculated to influence opinion in favour of that closer concern with problems of welfare, of nutrition and social and economic development, in place of the political problems with which British Colonial administration has been sometimes excessively concerned in the past.

Walter Bagehot once reminded us that the British Empire is in danger of falling through not understanding the greatness of the institutions which it has created. Co-operation between the United Nations cannot be based on the liquidation of the British Empire, but on its continuing evolution as a system of free co-operation. The achievements as well as the mistakes of the past must be recognized. The disasters in Malaya, Burma and Java must not lead us or our allies to forget that the links which hold together the British Commonwealth of Nations bore alone for more than twelve months the strain of the fiercest assaults upon the bastion of freedom in Great Britain. Mr. Churchill's words should rather stir us to remember the responsibilities of Empire and to make the Empire a shining example of the free and full development that can be achieved by democratic means.

Fortunately it is clear from Lord Cranborne's statement on behalf of the Government and other declarations that there is already a large measure of agreement among progressive opinion on the Colonial question in Great Britain and the United States. The general trend presupposes a minimum of internationa organization, sufficient to guarantee security from aggression and to promote economic stability. The pooling of Colonies under an international body is rejected in favour of the adherence of all Colonia powers to a Colonial charter, the raising of administrative and labour standards by a series of international conventions and the general supervision o Colonial administration by an international Colonia Commission. Furthermore, the development of the tropical Colonies is regarded as one of the major economic priorities before the world, and where the general consensus of opinion would part company from Mr. Wilkie is in regarding this question of development not as one for a rigid time-table but rather of how to raise the standard of existence in these backward areas with optimum rather than the maximum speed.

This all pre-supposes a common outlook on Colonia questions and the wholehearted adoption not by any one Colonial power but by all the United Nations of this principle of guardianship, with its implication of full partnership in due course. With that presupposition would go an understanding which should facilitate co-operation in even wider fields. Moreover, whatever the precise form which the Colonial Commission may take under international organization, it must provide the necessary flexibility, so that organizations can be developed which are appropriate to the particular service required and the conditions of the community to be served. There must be vision and imagination, and the willingness to build on the best available experience from whatever source, rather than the attempt to copy slavishly the Tennessee Valley Authority, or any other particular type.

To fulfil its essential functions, whatever authority is established for co-operative attack on this great problem of Colonial development, the planning, advisory functions and financial assistance will require the help of an international research staff. Many of the problems are clearly far beyond the scope of the Colonial Development Fund already initiated by Great Britain. The survey of resources involved, with research into anthropology, water-power, mineral and forest reserves, soil erosion, agriculture, transport, marketing problems, health, trends of population and the prospects of export and import trade call for a common policy as well as for the resources of more than one Colonial power. The very effort involved should promote an understanding which would go far to eliminate some of the sources of friction which Colonies have provided in the past.

Appreciation of the fine work done by British administrators in the past suggests at once how fitting it is that Anglo-American co-operation should lead the way in the evolution of a new Colonial system. To treat the Colonial peoples as human beings, who are to be guided, helped and developed towards political and cultural equality, is in keeping with the finest traditions of both peoples. That new outlook was reflected in Mr. Eden's speech at Edinburgh last July, as well as in those of Mr. Wilkie, Mr. Appleby, and other American leaders. It was emphasized once more in General Smuts's historic speech. The United Nations cannot form the core of a better organized world and exclude Colonial policy from their common interest. The large principles of social policy, the principle of international help underlying the mutual aid agreements, like the large principles of international social and economic policy embodied in the Atlantic Charter, must apply to all humanity. The United Nations are already committed to improved standards of living for the peoples of the world and to the promotion of an expanding and non-discriminating trade. As we take up that task in association with the United States, and seek to forward the health and welfare of all peoples, Colonial or not, there will be cultivated a new spirit of human solidarity, and economic conditions can be established which strike at the root causes of war and lay deeper foundations for world peace. The whole tradition and history of Great Britain and the United States make it fitting that together they should lead the way, and their ability to formulate a common policy and reach full understanding on Colonial questions is a touchstone of their capacity for world leadership in the wider areas covered by the Atlantic Charter. But that partnership must be based on full knowledge of each other's achievements, and appreciation of what is good and valuable in those achievements; and the first condition of success is that the task of understanding should be attempted now with honesty and sincerity.

BEARING OF MODERN RESEARCHES ON EVOLUTION

Evolution

The Modern Synthesis. By Dr. Julian Huxley. Pp. 645. (London: George Allen and Unwin, Ltd., 1942.) 25s. net.

IN the four decades from the publication of the "Origin of Species" in 1859 to the end of the nineteenth century, evolution held the centre of the stage in biology. With the rediscovery and confirmation of the facts and theories of Mendelian inheritance in 1900, there followed a period of intensive study of variations and their modes of transmission. To a considerable extent the early work on mutations prepared the way for the rapid development of experimental methods in the study of heredity. In due course Mendelian theory became closely associated with modified concepts of mutations and with certain aspects of chromosome structure and behaviour. It remains an interesting historical fact that during the first three decades of the twentieth century evolutionary concepts developed very little; indeed, in some biological circles evolution was almost a taboo subject. The position may be accurately gauged by the general tone of Bateson's presidential address at the British Association's meeting in Australia in 1914, approximately in the middle of this period, and even by the following single sentence from this address: "It is no time to discuss the origin of the Mollusca or of Dicotyledons, while we are not even sure how it came to pass that *Primula obconica* has in twenty-five years produced its abundant new forms almost under our eyes". A further change in biological thought has become evident during the past ten years. To a certain extent, there has been a move back in interest and emphasis from heredity to evolution, but advance is marked by the acceptance of new theories, while the old theories are in part strengthened and in part discarded.

The above generalizations have many exceptions and the terms of years suggested do not fix exact limits to complete saltations of subject, method or theory. There is, however, no doubt that many biologists feel that the time has arrived when the discoveries of the past thirty or forty years, in cytogenetics and ecology in particular, should be applied to the more extensive problems of evolution and, it may be added, of systematics. No one has more clearly visualized the need for such a synthesis and the wide field of possibilities it opens up than Julian Huxley. His wide and sympathetic approach to evolutionary problems was clearly shown in his introductory chapter and general editorship of "The New Systematics" (Oxford, 1940) and is set forth in much greater detail in this new book. These two volumes probably mark the first stages in the renewed fight against isolationism in biology. Special researches must continue, but it is becoming more and more clearly recognized that their results often have a deeper and wider significance than the specialist himself realizes. Biologists are fortunate in having had made available in book form not a culling from thirty-five pages of references but a concise synthesis of an extensive range of modern knowledge upon evolution. It is of particular importance that this work should be published now. A very large number of biologists have had their work interrupted or deflected by special service in or for the war effort. It may be hoped and expected that in the years of peace to come "Evolution: the Modern Synthesis" will serve as a restarting point for many of us, and will also act for a very long time as a stimulus to those who will become biologists under what may be quite new conditions.

It is impossible to review at any reasonable length the detailed contents of this volume. It is, however, not difficult to indicate its main features and conclusions. Three conclusions stand out strikingly: that natural selection of variations, with some modifications of Darwin's point of view, is the most important known means by which evolution is directed; that variations themselves originate in many ways and are correspondingly diverse; and that neither mutational variation nor selection alone is creative of anything important in evolution, though the two in conjunction are creative. Both variation and selection are shown to be far more complex than could possibly have been realized but for very recent researches. The multiformity of evolutionary processes is almost as great as the heterogeneity of the results. The essential synthesis is between the kinds and methods of variation and the kinds and methods of selection leading to the diversification of organisms. This diversification is expressed in taxonomic schemes of a hierarchical nature, and, for a variety of reasons, interest has particularly centred around speciation.

Acceptance of the mutation theory, in its modern form, explains, up to a point, how variations arise. Mutations have been shown to involve many kinds of structure and many kinds of function. Moreover, they are of all grades of importance in that differences arising particulately may be very considerable or very minute. Genes, and consequently mutated genes, combine to form different gene-complexes, and the gene-complex as a whole may influence the action and expression of any gene in the complex. Further light is thrown on variation, and on its converse, conservatism or stability, by many recent cytological and cytogenetical studies which have led to the discovery of inversions, translocations, reduplications, etc., within chromosomes, resulting in marked position effects, and to the widespread occurrence of polyploidy, especially in the plant kingdom.

The author devotes three chapters to the problems of speciation. These chapters contain a great range of facts and set forth very clearly many of the difficulties which taxonomists have to face. In actual practice the hierarchical system, of families, genera, species, etc., has been found to work better than any other for a wide range of purposes. It is, however, clear that there are a number of quite different *kinds* of animal and plant species—and the same is true for other taxonomic grades. Speciation may be essentially geographical, ecological, or cytogenetical. The clear and concise attempt (pp. 407–8) to tabulate "the main kinds of taxonomic units with concrete existence as natural groups" is very interesting in that it allows a wider range of categories than is at present orthodox in taxonomic circles, although it does not violate the International Rules of (Botanical) Nomenclature. It is doubtful if the categories here suggested are sufficient to cover all "natural groups" without sometimes forcing into the same "class" populations that are unlike in important and essential characters. Even if a very full survey of all existing "natural groups" that can be studied by the diverse methods of taxonomy, ecology, cytogenetics, and biogeography were made, and from the result a complete classification were made to cover adequately and without "lumping" all known living organisms, there would still remain a taxonomic problem of considerable magnitude. Evolution is not merely dynamic; it is, as shown in earlier chapters of the work under review, in the main a continuous process. Discontinuities, sometimes large, sometimes small, now occur in the products of evolution, but their 'reality', if the facts and conclusions of the first four chapters be accepted, is, with a minority of exceptions, of geologically recent date. If the fossil history of species, etc., be included in systematics, "the reality" of species (and of other taxonomic units) becomes a much more doubtful proposition and their classification correspondingly more difficult. It is, perhaps, not without significance that Huxley considers much of the fossil evidence, under the chapter heading "Evolutionary Trends", *after* he has dealt with speciation. It is, of course, arguable that it would be best to have two independent classifications—the one for extant organisms and the other for fossils. Neither would then be a general classification, complete to the limits of knowledge, and any proposal for such a dual classification, except as a tentative measure for special purposes, would appear antagonistic to the synthetic viewpoint taken by the author. The stress laid on the study of the discontinuities now occurring must be heartily welcomed and the author's discussion of this subject must surely focus research on a wide range of unsolved problems.

Dr. Huxley is a zoologist, but one with a very considerable knowledge of plants. The greater part of the evidence accumulated in "Evolution: the Modern Synthesis" is derived from studies of animals. There is, however, much botanical matter included in appropriate places. It is the fault of botanists themselves, or their fate, that relevant botanical material is not available for certain subjects. In particular, there is very little known about evolutionary trends in fossil series of plants, at least in comparison with the evidence available in certain invertebrate and some vertebrate groups. The chapter on "Evolutionary Trends" deals almost entirely with animal data. Again, ontogenetic studies in plants have been less successful in providing evolutionary suggestions than have ontogenetic studies in animals. On the other hand, it was from the study of plants that Mendelism arose, that mutations were first recognized and named, and that the importance of hybridization in evolution was first realized, perhaps because morphology and physiology have never been separated in botany to the extent they frequently are in zoology. Botanists will find the book of supreme interest from two general points of view: they will desire to add examples of evolution or inheritance, of structure or function, to the zoological and botanical examples given, thus supporting or modifying the conclusions reached by the author, and, secondly, they will obtain many suggestions, even from the more strictly zoological paragraphs, for investigation of plants from new points of view.

Every page causes one "furiously to think", not over obscurities of meaning, for the style is simple and clear and the vast majority of terms used will be known to any biologist, but over the actual facts set forth and the conclusions reached. Again, the very difficult feat has been accomplished of placing before the non-specialist scientific reader concise understandable accounts of recent important researches which were often difficult to follow in the original publications. The mathematical analyses of Fisher, Haldane, and Sewall Wright and the evolution of genetic systems are obvious, but not the only, examples. How the "layman interested in biology" will "find the book suited to his needs" must be decided by the layman. It would appear most definitely and admirably to meet the need of a very wide range of biologists for a synthesis of modern evolutionary fact and theory. W. B. TURRILL.

CHILD PSYCHOLOGY

The Natural Development of the Child

A Guide for Parents, Teachers, Students and Others. By Dr. Agatha H. Bowley. Pp. xvii+172+32 plates. (Edinburgh: E. and S. Livingstone, 1942.) 8*s*. 6*d*. net.

THIS small book is timely. The struggle to obtain recognition of the child guidance clinic as a necessary part of the educational system of Great Britain (and as part of preventive social medicine) is drawing to an end. It has created a need for easily accessible, readable and compact literature on the subject. Some need a general description of the work of a clinical team, while others ask for a text-book. Dr. Bowley's book does not meet either of these needs at all completely (and it was not her aim to satisfy them), but both classes of potential readers will find it very useful. The author has drawn upon a rich personal experience and upon wide reading, providing us with a very clear and concise summary of her knowledge. Her views are based upon the facts she knows so well, and her judgment remains independent.

The contents of the book necessarily range beyond the limits suggested by the title. The purpose is to describe the normal development of children, but since this cannot be achieved without comparison with abnormal variants, much of the book is concerned with pathological symptoms with suggestions for their treatment. The basis of the treatment is, however, the study of the normal child. The author describes the successive stages of child life briefly, but very clearly, very properly giving the pre-school child a large share of her space. She states the developmental norms which have been established by research workers briefly and usefully, and she could scarcely have done this better within such narrow space, but as Dr. MacCalman points out in the foreword, norms for the development of personality are much more difficult to establish than those for intellectual processes. This point is insufficiently stressed, and readers without experience in this field may be led to suppose that the checking up of general development is a more simple and certain procedure than it is. The standards the author mentions require careful interpretation based on a background of wide knowledge and experience. Teachers have this background, and to them the book can be recommended without reserve. It should prove exceptionally useful in training departments. But ordinary parents without specialized training (and with little opportunity of comparing children) need to be very cautious, though they can learn usefully from it. We hope they will not be induced to watch the stage by stage development of their children too closely or too anxiously. A few illusions about our sons is no great handicap to their upbringing.

The one demerit of the book is due to its small size. It is impossible to deal adequately with so wide a subject in 168 pages, and Dr. Bowley's desire to be comprehensive causes her statements to appear arid and dogmatic. The bibliographies provided would have been much more useful had there been space for fuller discussion in the text. Probably war-time restrictions have affected the scale of the volume, but if so it would have been better to buy more room for discussion and case-histories by sacrificing the plates, for charming as they are they add little to the information given in the text. So the book will be most useful if regarded as a very good notebook, and if used side by side with such a book as "A Survey of Child Psychiatry" (edited by R. G. Gordon, Oxford, 1939) both will gain in value.

A. W. WOLTERS.

A NIGERIAN KINGDOM

A Black Byzantium

The Kingdom of Nupe in Nigeria. By Dr. S. F. Nadel. (Published for the International Institute of African Languages and Cultures.) Pp. xv+420+16 plates. (London, New York and Toronto: Oxford University Press, 1942.) 25*s*. net.

SOME forty-five years ago, while the eyes of Great Britain were fixed on South Africa, Sir Frederick (now Lord) Lugard was quietly taking up the task of bringing ordered government into Northern Nigeria. This vast territory then consisted of a network of States under Muhammadan rulers who acknowledged the suzerainty of the Fulani Sultan of Sokoto. These States had attained a remarkable degree of political and military organization; but, as the social and economic system was based on slavery, this organization had been used to devastate the pagan tribes in a perennial hunt for slaves. When Sir Frederick Lugard assumed control in 1900, on behalf of the British Government, Northern Nigeria was in a state of complete chaos. To-day it is one of the most contented and prosperous portions of the British Colonial Empire.

Among the most powerful of the States forming the Fulani confederacy was the kingdom of Nupe. Situated on the Middle Niger, this State had been a thorn in the side of the Royal Niger Company, carrying out slave-raiding expeditions, sometimes to within a few miles of the Company's trading stations. In 1897 the Company had to send a military expedition against Bida, the capital city of the Nupe. The Nupe army was defeated and the Emir or Etsu, Abubakr, was driven out. But as soon as the British troops had retired Abubakr returned and resumed his defiant attitude. In 1901 Sir Frederick Lugard was compelled to take military action for the second time, Abubakr again fled, and was replaced by a prince named Mohamadu, who, like many of the other Fulani rulers of Nigeria, became a loyal supporter of the British regime. The day before his death, in 1916, Mohamadu told the writer of this review that the secret of the friendly acceptance of British rule by the peoples of Northern Nigeria was the consideration which had been shown from the outset to native institutions, and in particular to the Muhammadan religion.

The present volume, "A Black Byzantium", is a description of the Nupe kingdom, viewed mainly from the political and economic side. It is the work of Dr. Nadel, now the Government anthropologist in the Anglo-Egyptian Sudan. Dr. Nadel spent two years (1934–36) in Nupe, working as a Rockefeller fellow under the auspices of the International Institute for the Study of African Languages and Cultures, of which, incidentally, Lord Lugard is the distinguished chairman. He brought to his task a thorough knowledge of the technique of scientific investigation and soon established close and friendly relations with the Nupe, helped by his speedy mastery of their difficult language.

The Nupe people are far from being a simple or 'primitive' people. Indeed, the cultural differences within the tribe are so considerable that one of Dr. Nadel's principal difficulties was to discover representative sections. It was mere chance, he observes, that brought to his knowledge the discovery that in one small village there was a matrilineal system of succession to chieftainship, although Nupe society is conspicuously patrilineal, while in another village he stumbled on a ritual which amounted to a symbolic 'king-killing'—a usage for which there is no parallel in any other part of Nupe-land.

Chapter 2 deals with culture, tribe and society; Chapter 3 with the kinship system; and Chapter 4 with the general community, the pattern of whose life in the villages is very different from that in the towns. Then comes a close examination of the political organization. Nupe was a feudal State, divided into smaller and larger districts each administered by a feudal lord. These lords lived at the capital and rarely visited their possessions, but were responsible to the king for law and order in their districts. The fiefs were attached to certain offices or titles, and one of the weaknesses of this system was that promotion to a higher rank involved a re-shuffling of the fiefs. Besides these feudal lords there were numerous other titled officials, and included in the hierarchy were the heads of the craft-guilds, whose incorporation was a corollary of the control exercised by the State over all the more important industries. The king himself enjoyed many economic privileges, and one of these was the monopoly of the trade in kola-nuts, which are famous all over West Africa.

Slavery in Nupe-land carried with it no great stigma. Slaves, indeed, could rise high in the service of the king and might own lands or even fiefs. Another feature of Nupe society was the institution of clientship—the voluntary allegiance of a free individual to some feudal lord or other influential personage, with the view of securing his patronage and protection. Such a relationship involved on the client's part gifts, services and a regular tithe, and on the part of the protector help against claims, just or unjust, grants of land, and assistance in numerous other ways. Nupe society, indeed, was built up on a basis of class distinction. The prerogatives of the nobility were many and extended even to matters of dress, so that no commoner would dare carry a sword or wear a blue turban. In these decadent days there is a new symbol of social status—an alarum clock carried in a wooden case by the body-servants of men of rank!

Chapter 10 gives a description of government in modern Nupe. This proceeds on the general principle of indirect rule, and when Dr. Nadel says that agreement between the Etsu (king) and the British district officer is necessary for every administrative measure he must mean for every measure of major importance. A disturbing fact that emerges from Dr. Nadel's study of family budgets is the very heavy burden imposed on the poorer classes by the Government tax, small as it appears to be. The system, too, of collecting tax on an individual basis ignores the fact that the primary social unit of the Nupe is the large extended family—a co-operative body in which the poorer members are helped by the wealthier. Again, in the realm of law, there are the difficulties caused by the application of dual systems—the Muslim Sharia and the traditional law of the Nupe. Under the former, for example, property and land left by a family head are divided equally among sons—a practice which in Nigeria, as elsewhere in the Muhammadan world, has led to an excessive fractioning of the land. But under the indigenous system land and other property are inherited by a younger brother—the sons staying on the land and working with the brother's sons under the heir as their sociological father. In this way landed property is kept intact.

Coming now to economics, there is a lot of valuable information about the land-tenure system, although it is not always clear whether the writer is referring to past or present conditions. Land is freely borrowed, there are long-term leases, purchase, and primary and secondary tenantships of hereditary land. It may be observed that in Nigeria as a whole there is need of a great deal more information about native systems of land tenure. Little is known, for example, about the relations of landlord and tenant, the extent of sales, and so on. The land policy of Northern Nigeria has always been regarded as a model for other Colonies, and it has worked well in practice, so far. Yet where all lands are declared to be native lands and are also at the disposal of the governor, it is not clear what exactly is the legal position, especially since native custom regarding land tenure is in a state of rapid transition.

Dr. Nadel provides a great deal of information about agricultural production, the organization of labour, the various forms of collective labour, and the part played by women in the marketing of crops. Of particular interest are the descriptions of the guilds of blacksmiths, beadmakers, weavers and glass workers. There are chapters also on industria labour, wealth and other economic subjects. The book concludes with an account of the system of education for citizenship.

Dr. Nadel has an excellent command of English although he occasionally gives vent to bursts of jargon, as when he speaks of "an ideology heedless of empirical facts supplying the conceptual background for a social configuration"! There are also some historical slips. The dates of Etsu Mohamadu and Etsu Bello are wrongly given. Altogether "A Black Byzantium" is a most valuable contribution, particularly, on the economic side, to the much needed wider knowledge of Nigeria.

C. K. MEEK.

SYNTHETIC RUBBER

Modern Synthetic Rubbers
By Dr. Harry Barron. Pp. viii+274. (London: Chapman and Hall, Ltd., 1942.) 25*s.* net.

THE very title of the book is unacceptable to the technical mind: one speaks of "Hymns Ancient and Modern" and "Modern Furniture" but not of "modern" synthetic rubbers or indeed of any "modern" technical products. After reading the book the author's preface will be found most illuminating; for example, he states, "I have endeavoured to bring together as much of the information available in as palatable a form as possible", yet in so doing the author has written a book which is too technical for the general reader or even the average rubber technologist and too inaccurate for those seriously interested in synthetic rubber. Such statements, which occur frequently, as "Polyisobutylene is a polymer of isobutylene" are meaningless to the layman and redundant to the chemist. Some errors will be detailed below; they would appear to have arisen in two ways: first, by repeating existing published errors and, secondly, by the evident anxiety of the author to fill up gaps in existing knowledge. In some cases the author is actually in conflict with himself; for example, on p. 175 the reader is told "the first commercial synthetic rubber was neoprene", but on p. 214 the reader is asked to revise his views since: "The first commercially synthetic rubber to appear on the American market, was an ethylene polysulphide polymer designated as Thiokol". Another example is that on p. 201 the reader is informed that polyisobutylene has the greatest temperature range of elastic properties, but on p. 208 he is told that this record is held by butyl rubber.

Another somewhat regrettable feature of the book is one which the author has again deprecated in his preface, namely, the synthetic versus natural rubber controversial attitude, which may be all very well in technical journalism, a field in which the author is a recognized personality, but is undesirable in what purports to be a serious text-book. The solution to this controversy will be settled by hard technical and economic facts and not by political and journalistic pleadings.

In the chapter on the economics of synthetic elastic materials the author states that there has been considerable rivalry in the United States between petroleum interests, chemical interests and rubber manufacturers for leadership, but in fact the rivalry has been between the petroleum and agricultural interests over the raw material for butadiene. This has now been settled by allocation. It was generally recognized from the commencement of the campaign that the bulk of the polymerization work would be carried out by the rubber manufacturers, whereas the butadiene would be produced by petroleum and agricultural interests and 'second monomers' by the chemical and to a lesser extent by the petroleum interests.

Another curious characteristic of this book is that while the author bewails the almost entire absence of technical prowess in natural and synthetic rubber in Great Britain he fails to give credit to British work where it is due; for example, on p. 186, the use of chlorinated rubber for bonding neoprene to metals is attributed to Yerzley, but in fact it was discovered in Great Britain by Habgood. After reading p. 121, the conclusion would be reached that the pioneer work on the constitution of copolymers had been carried out in the U.S.S.R., since no mention has been made of the work in Great Britain of Hill, Lewis and Simonsen.

One of the greatest mistakes in the book is the failure (p. 70) of the author to realize that the discoverer of synthetic dyestuffs was not the same Perkin as the one that attempted to develop synthetic rubber in Great Britain in 1912, but his father.

In the general discussion of the relative merits of natural and synthetic rubber two important generalizations have been missed, namely, that natural rubber is superior to all synthetic rubbers in cutting and tear-resistance, and that the superior resilience of natural rubber is only true at normal room temperatures.

The author puts forward a terminology which he states to be simple and conforming to current practice. It is not simple because many of the products could be equally well put in two or more groups; thus 'butyl rubber' could be an 'elastomer' since it is based partially on butadiene, or an 'elastene' because it is based partially on an olefine, or an 'ethanoid' because butadiene is divinyl. Current practice is to call all these products collectively synthetic rubbers (since, as pointed out by the author, it is the properties, and not the product, which are desired) and individually by their trade names.

Many now generally recognized erroneous ideas are given in the book as, for example, that rubber is the *trans* isomer of polyisoprene (p. 63) and that rubber is formed by polymerization of isoprene in the tree (p. 124). Several wrong ideas could be drawn from the chapter on "Emulsion Polymerisation"; for example, the author sets out to give the impression that this work was undertaken "to simulate the simple processing of nature" whereas it was an inevitable development based on the rapidly developing field of physical chemistry with its growing knowledge of surface action and emulsification. The author regards emulsion polymerization as the solution of all polymerization difficulties and his love of false analogies has carried him into stating: "The position is roughly analogous to the change-over from wild uncultivated natural rubber to the carefully graded pleasant [!] plantation rubber of to-day", whereas those who have had any experience of emulsion polymerization know (a point emphasized by Carothers) that the control of this type of reaction is far from perfected. The author has also mixed up the Russian synthetic rubbers thus: on p. 70 he states that *SKB* is made from alcohol whereas on p. 142 he makes the assertion that it is made from petroleum.

The section on butyl rubber displays a lack of knowledge of the design and polymerizing conditions for this important group of rubbers. The sentence on p. 205, "An aliphatic iso mono-olefine such as isobutylene and a hydrocarbon compound having a conjugated system of alternate single and double bonds and having at least one olefine linkage, e.g. butadiene, isoprene, or styrene, are treated. . . ." is meaningless (and inaccurate) in a text-book. Furthermore, the author apparently is under the impression that isobutylene and butadiene will copolymerize in almost any proportions in which the experimenter mixes them, but this is, of course, not the case. Butyl rubber is described as a white material but no mention is made of the fact that the whiteness is due to zinc oxide put in by the manufacturer.

Some inaccurate information is given about the composition and constitution of the common commercial synthetic rubbers. How can, for example, "the basic recurring group" (p. 34) of a simple copolymer containing 25 per cent of one monomer contain one molecule of each monomer ? The suggestion is made (p. 177) that the superiority of Neoprene *G* over Neoprene *E* is due to its production by emulsion technique, but the fact is overlooked that Neoprene *E* was also eventually made by the same technique. Thiokol *F* is not derived from dichlorethyl formal (p. 216). The section about Hycars is confused and the uninformed reader might assume that importance is attached to Hycar *OR* for tyres. The section on Chemigums is equally indefinite and would lead the reader to believe that these rubbers had no similarity with Buna *S* or *N*. There are also several errors in the simple technology of the rubbers; for example, the statement is made on p. 206 that butyl rubber is difficult to work on a cold mill but becomes soft and smooth and amenable between 80–100 degrees (no scale of temperature given), whereas anybody who has ever handled this product knows that it runs smoothly on a cold mill but 'breaks' up on a hot one. On p. 59 the statement is made that a solution of chlorinated rubber is invariably employed for bonding synthetic elastic materials to metal. This is far from the truth, since with the sulphur-curing synthetic elastic materials the brass-plating technique is almost invariably employed.

In defence of the author it must be said that he has attempted to write about the subject at the most difficult time in its history, when products and ideas are changing and few technologists in Great Britain have had the opportunity of actually handling the new synthetic rubbers.

The general lay-out is good and it is a great pity that the book has been spoilt by so many mistakes.

W. J. S. NAUNTON.

THE HIGH-SPEED COMPRESSION-IGNITION ENGINE

The High-Speed Compression-Ignition Engine
By C. B. Dicksee. Pp. xii+331. (London, Glasgow and Bombay : Blackie and Son, Ltd., 1940.) 16*s*. net.

THIS is the work of an engineer who has been intimately connected with the application of high-speed compression ignition engines to public passenger vehicles over the whole fourteen years of this development. He has been responsible for the power units of the majority of London's oil-engined buses and nobody will question the high technical standard these have reached. Improvements are so gradual that they usually pass unnoticed by the public, but a comparison of the state of the atmosphere in a traffic block on a hot summer's day in, say, 1939, with that in 1929, indicates the progress in combustion efficiency, lubrication, etc.

In his book, the author, with this wide experience to support him, has wisely written from his own point of view. He has, of course, found it necessary to call on the work of others, but the reasoning throughout is original and most of the experimental data are the results of his own researches. Proceeding from a brief but adequate treatment of the available basic knowledge of the properties of gases and of the processes of combustion, he discusses the various problems of practical design in a very able manner, endeavouring always to interpret practical results in terms of fundamental knowledge. His work thus preserves a better balance between theory and practice than is often found in books on this subject.

Following his first three chapters, which deal, respectively, with the laws of gases, ideal cycles and combustion, he discusses the losses and limitations of the practical engine. In this chapter, among other good points, he gives suitable prominence to the 'practical ideal' curve of efficiency of Tizard and Pye, which marks a great step forward from the air standard cycle to which many writers continue to devote so much attention. This is followed by a useful chapter on volumetric efficiency and the air charge.

The next two chapters, dealing, respectively, with the processes of combustion and the air movement in the combustion chamber are the author's best. The discussion of the interaction of the variables which determine the course of the ignition lag and subsequent combustion is masterly, the section dealing with the function of air movement being exceptionally good. A minor point is that the later Cambridge experiments carried out by Wolfer, under Bird's direction, are not considered, the author referring, on pp. 111 and 198, only to Bird's early work on ignition lag.

The author, in the next chapter of twenty-three pages, discusses types of combustion chamber. This discussion, while always sound in its reasoning and of great interest, suffers from incompleteness : for example, the Junkers design is omitted, in spite of the practical success achieved in aircraft and over the whole range of oil engine practice, while the General Motors engine would also merit consideration. But lack of space may have been the reason for this. The author unfortunately prefers the term "pre-combustion chamber" to "designs with ante-chambers".

This chapter is followed by one dealing with the somewhat difficult subject of fuel injection. Here the author reveals a defect of his good qualities, since, in his desire to correlate his own observations with fundamental principles, he neglects to use other experimental evidence available in British publications. In dealing with processes in the piping, therefore, he is at his best when dealing with engine results of a direct kind, in which the practical value of his evidence is high.

The book concludes with a valuable chapter having the title, "Some Practical Results". The discussion of the measurement of mechanical losses is interesting, but in most engines the third method, namely, of extrapolating the curve of fuel per hour on brake mean pressure, leads to values that are too high. The author, however, correctly says "that there is no method which will give a really accurate measurement of the indicated horse power". Under the heading, "Future Developments", and, indeed, throughout the book, no real reference is made to two-stroke engines. While the author obviously does not wish to deal with such engines, a mention of this limitation might have appeared in the preface. But none of the minor criticisms offered affect the fact that this work is of quite exceptionally high standard and value.

S. J. DAVIES.

THE BEVERIDGE SECURITY PLAN

SIR WILLIAM BEVERIDGE'S report on social insurance and allied services* has already been widely discussed, and it seems desirable to put on record its main features. The report includes, in discharge of its first duty, a comprehensive survey of social insurance and allied services as they exist to-day in Britain. This survey, showing just what provision is made, and how it is made, for different forms of need, is set out in Appendix *B*. The picture presented shows that provision for most of the many varieties of need through interruption of earnings and other causes that may arise in modern industrial communities has already been made in Britain on a scale not surpassed and scarcely rivalled in any other country. In respect of limitation of medical services Britain's achievement falls seriously short of what has been accomplished elsewhere, and its provision for cash benefit for maternity and funerals and its system for workmen's compensation are behind other countries. Secondly, social insurance and the allied services, as they exist to-day, are conducted by a complex of disconnected administrative organs, proceeding on different principles, doing invaluable service but at a cost in money and trouble for which there is no justification. In a system of social security better on the whole than can be found in almost any other country, there are serious deficiencies; by closer co-ordination, the existing social services could be made at once more beneficial and more intelligible to those whom they serve and more economical in their administration.

In proceeding from this comprehensive survey to the second duty, that of making recommendations, Sir William Beveridge lays down three guiding principles. First, any proposals for the future, while they should use to the full the experience gathered in the past, should not be restricted by consideration of sectional interests established in obtaining that experience. Secondly, organization of social insurance should be treated as one part only of a comprehensive policy of social progress. Thirdly, social security must be achieved by co-operation between the State and the individual. In offering security for service and contribution, the State should not stifle incentive, opportunity and responsibility; in establishing a national minimum, it should leave room and encouragement for voluntary action by each individual to provide more than that minimum for himself and his family.

The plan for social security set out in the report is based on these principles. It uses experience, but is not tied by experience. It is a limited contribution to a wider social policy in which not only want but also those other giants on the road to reconstruction—disease, ignorance, squalor and idleness—are attacked. It is first and foremost a plan of insurance, a scheme of social insurance against interruption and destruction of earning power, and for special expenditure arising at birth, marriage or death. The scheme is based on six fundamental principles: flat rate of subsistence benefit; flat rate of contribution; unification of administrative responsibility; adequacy of benefit; comprehensiveness; and classification. Its aim is to make want unnecessary.

The proposals are set forth in detail because the principles underlying any practical reform can only be judged by seeing how they would work in practice, and also because if a plan for social security is to come into operation when the War ends or soon after, there is no time to lose in getting the plan prepared as fully as possible. The plan covers all citizens without upper income limit, but has regard to their different ways of life. In relation to social security, the population falls into four main classes of working age and two others, below and above working age. These four classes consist of employees, or persons whose normal occupation is employment under contract of service; others gainfully employed, including employers, traders and independent workers of all kinds; housewives, or married women of working age; and others of working age not gainfully employed. All these four classes will be insured for security appropriate to their circumstances, and all classes will be covered for comprehensive medical treatment and rehabilitation and for funeral expenses. Maternity grant, provision for widowhood and separation and qualification for retirement pensions will be secured to housewives by virtue of their husbands' contributions, while in addition to maternity grant, housewives who take paid work will receive maternity benefit for thirteen weeks to enable them to give up working before and after childbirth. All persons in the remaining three classes of working age will pay a single security contribution on a single insurance document each week or combination of weeks. In the first class the employer will also contribute, affixing the insurance stamp and deducting the employee's share from wages or salary. The contribution will differ from one class to another, according to the benefits provided, and will be higher for men than for women.

Subject to simple contribution conditions, all employees will receive benefit for unemployment and disability, pension on retirement, medical treatment and funeral expenses. Employers and other independent workers will receive all these, except unemployment benefit and disability benefit during the first thirteen weeks of disability. Those of working age not gainfully employed will receive all these except unemployment and disability benefit, but as a substitute for unemployment benefit, training benefit will be available for those in both these classes to assist them to find new livelihoods if their present ones fail. Unemployment benefit, disability benefit, basic retirement pension after a transition period, and training benefit will be at the same rate, irrespective of previous earnings, providing by itself the income necessary for subsistence in all normal cases. There will be a joint rate for a man and wife who are not gainfully occupied. Disability due to industrial accident or disease will be treated like all other disability for the first thirteen weeks; thereafter disability benefit at a flat rate will be replaced by an industrial pension related to the earnings of the individual, subject to a minimum and a maximum. After a period of unemployment, benefit will normally be subject to a condition of attendance at a work or training centre.

Pensions other than industrial will be paid only on retirement from work and may be claimed at any time after sixty-five for men and sixty for women, the rate of pension being increased above the basic rate if retirement is postponed. Medical treatment covering all requirements will be provided for all citizens by a national health service organized under the health departments, and post-medical rehabilitation treatment will be provided for all persons capable of profiting by it. A Ministry of Social Security will be established, responsible for social insurance, national assistance and encouragement and supervision of voluntary insurance, and will take over, so far as necessary for these purposes, the present work of other Government Departments and of local authorities in these fields.

---

* Social Insurance and Allied Services. Report by Sir William Beveridge. (Cmd. 6404.) Pp. 299. (London: H.M. Stationery Office, 1942.) 2*s*. net.

All the principal cash payments will continue so long as the need lasts, without means test, and will be paid from a Social Insurance Fund, built up by contributions from the insured persons, from employers, and from the State. This is in accordance with the view that benefit in return for contributions, rather than free allowances from the State, is what the people of Britain desire, and that the money required should come from a fund to which the recipients have contributed and to which they may be required to make larger contributions if the fund proves inadequate. The scheme thus preserves the contributory principle, but it also involves a pooling of risks except so far as separation of risks serves a social purpose; there is no longer an admitted claim of the individual citizen to share in national insurance and yet to stand outside it, keeping the advantage of his individual lower risk, whether of unemployment or of disease or accident.

In this plan, which is in some ways revolutionary but largely a natural development, and could be put in operation in the immediate aftermath of the War, there are two features which call for particular note. First, it involves superseding the present system of approved societies giving unequal benefits for compulsory contributions—a system which is inconsistent with the policy of a national minimum, has disadvantages for insured persons and involves unnecessary administrative costs—although there is suggested retention of the association of 'friendly societies' with national health insurance on a new basis. Secondly, it involves superseding the present scheme of workmen's compensation and inclusion of provision for industrial accident or disease within the unified social insurance scheme, subject to (*a*) a special method of meeting the cost of this provision and (*b*) special pensions for prolonged disability and grants to dependants in cases of death due to such causes.

In the forty-five years of its existence, the present system of dealing with the results of industrial accident and disease has, the report concludes, contributed little or nothing to the most important purpose of all, restoration of the injured employee to the greatest possible degree of production and earning as soon as possible. Post-medical rehabilitation has only just begun to receive practical attention. Costs of administration are higher in relation to workmen's compensation than they need be or than they are in compulsory social insurance, while the system affords no complete security for the payment of compensation and fails to secure maintenance of necessary income.

On balance, the reasons for distinguishing between accident and industrial disease in any employment and other causes of injury outweigh the reasons in favour of complete uniformity. The report also maintains that there is a good social reason for taking a different line, in part at least, about the dangers of industrial accident and disease. Accordingly, one part of the funds required for benefits, pensions and grants in respect of industrial accident and disease will be obtained by a levy on employers in industries scheduled as having materially more than the normal risk of accident or industrial disease as a whole. The levy will not cover the whole of the excess cost above the normal but only a prescribed proportion, and will be based on wages paid and on the degree of risk, so that it can be raised or lowered as the risk in any such industry or in any particular place of employment is found to be above or below expectation.

Exactly what industries should be scheduled as hazardous is a matter for further detailed inquiry, but the report makes an additional important proposal in regard to the machinery of administration. It is suggested that, in each industry scheduled as hazardous, and liable to the special levy, there should be set up a statutory association of employers and employees to deal with the problem of industrial accident and disease. The functions of such an association might include the promotion of safety in the industry, by co-operation with the department or departments responsible for safety regulations, by research into the causes of accidents, by propaganda and instruction, and in other ways; the promotion of measures for rehabilitation and re-employment in that industry, in co-operation with the general national organs for that purpose covering all industries; advice on the making of all regulations affecting safety in the industry, the scheduling of industrial disease, and methods of assessment of earnings; collecting from individual employers their quotas of the total levy required in the industry, in accordance with a scheme to be prepared by the association and approved by the Ministry of Social Security; and the establishment of schemes to supplement the benefits statutorily secured to all injured employees.

The statutory associations should combine the management and the labour in each industry, and the main purpose of the proposal is, within the framework of general social security, to utilize the knowledge, initiative and interest of those concerned in each industry, first, in making it as safe as possible, and, secondly, in mitigating so far as is humanly possible the consequences of those accidents and injuries that defy prevention.

In regard to the administration of the scheme by a new Ministry of Social Security, the report contemplates the establishment of a Social Insurance Statutory Committee, of an advice bureau for citizens in every local Security Office, and of a Division of Statistics and Intelligence, under first-rate leadership and with adequate reserves, to make use not only of its own material but also of the experiences of other countries. The Ministry should be able to make grants for research in all matters where further knowledge might reduce the burdens on the Social Insurance Fund. Provision is to be made to prevent hardship to persons employed in the administration of the present insurance schemes who are displaced as a result of the changes and for whom suitable alternative employment is not available; but while social security under the new system will involve no great increase, if any, in the number of officials, it is unlikely to make large numbers of those now employed redundant at any early date.

The scheme involves three particular assumptions which are discussed in detail in the last part of the report. The first of these is a general scheme of children's allowances. Social insurance should be part of a policy of a national minimum, and a national minimum for families of every size cannot be secured in practice by a wage system which must be based on the product of a man's labour and not on the size of his family. The view is taken that children's allowances are essential if benefit during unemployment is not to be allowed to equal or exceed earnings during work. They should be non-contributory, provided wholly out of taxation, and not to any extent out of insurance contributions. Accordingly the report recommends that children's allowances should be provided at the cost of the Exchequer in respect of all children other than the first child when the parent is earning, and of the first child in addition during the interruption of earning. The actual allowance should be graduated according to the age of the child and a cash allowance of 8s. a week on an average, administered by the Ministry of Social Security, is suggested.

The second assumption is comprehensive health and rehabilitation services for prevention and cure of disease and restoration of capacity for work, available to all members of the community. This is in accordance with the definition of the objects of medical service as outlined by the Medical Planning Commission of the British Medical Association in its draft interim report. While no detailed proposals are advanced in the Beveridge report, it suggests the need for a further immediate investigation, in which the finance and the organization of medical services can be considered together, in consultation with the professions concerned and with the public and voluntary organizations which have established hospitals and other institutions. From the point of view of social security, a health service providing full preventive and curative treatment of every kind to every citizen without exception, without remuneration limit and without an economic barrier at any point to delay recourse to it, is the ideal plan. Accordingly it is proposed that the social security contributions shall include a payment in virtue of which every citizen will be able to obtain whatever treatment his case requires, at home or in an institution, medical, dental, or subsidiary, without a treatment charge.

In regard to rehabilitation, the report advances three general propositions. Rehabilitation must be continued from the medical through the post-medical stage until the maximum of earning capacity is restored, and a service for this purpose should be available for all disabled persons who can profit by it irrespective of the cause of their disability. Cash allowances to persons receiving rehabilitation services should be the same as training benefit, including removal and lodging allowances where required, and thirdly, the contributions paid by insured persons should, as with medical treatment, qualify them for rehabilitation service with further payment. The organization of the rehabilitation service is already under examination by the Ministry of Labour and National Service.

The third assumption, on which the whole report is based, is the maintenance of employment and the prevention of mass unemployment. Payment of unconditional cash benefits as of right during unemployment is satisfactory provision only for short periods of unemployment; after that, complete idleness even on an income has a demoralizing effect. The report proposes therefore that, after a certain period, unemployment benefit should be conditional upon attendance at a work or training centre. Not only is this proposal impracticable if it has to be applied by the hundred thousand, but also the only satisfactory test of unemployment, an offer of work, breaks down in mass unemployment. The probable and possible effects of the Plan for Social Security in stabilizing the demand for labour are among its advantages, but they are subsidiary and do not touch the main problem of maintaining employment. For that, other measures are needed, and unless such measures are prepared and made effective, much that otherwise might be gained through the Plan for Social Security will be wasted.

The Plan for Social Security thus advanced cannot be judged without reference to the concluding section of the report, in which the abolition of want as a practicable post-war aim is discussed. The rise in the general standard of living in Britain during the last thirty or forty years demonstrates, first, that growing general prosperity and rising wages diminished want but did not reduce it to insignificance, and, secondly, that it is wrong to assume that the present War must bring economic progress for Britain, or for the rest of the world, to an end. New measures are needed to spread prosperity, and the plan is designed to meet that need. Freedom from want, in Sir William Beveridge's view, can be regarded as a post-war aim capable of early attainment on four conditions: after the War the nations must set themselves to co-operate for production in peace, rather than to plot for mutual destruction by war, whether open or concealed; the re-adjustments of British economic policy and structure that will be required by changed conditions after the War should be made so that productive employment is maintained; a plan for social security, that is to say, for income maintenance, should be adopted free from unnecessary costs of administration and other waste of resources; and finally, decisions as to the nature of the plan should be taken during the War.

If a plan for freedom from want, so far as social security can give it, is to be ready when the War ends, it must be prepared during the War. The decisions required now are of principle and execution —the decision to introduce a unified comprehensive scheme of social insurance, the decision to entrust administration of the scheme to a Ministry of Social Security, and the decision to appoint some person or body to prepare the necessary legislation and bring the scheme into being, so that it is ready when the War ends. The plan is put forward as part of a general programme of social policy and as a contribution towards the achievement of the social security named in the fifth clause of the Atlantic Charter. The report makes the points that the purpose of victory is to live into a better world than the old world; that each individual citizen is more likely to concentrate upon his war effort if he feels that his Government will be ready in time with plans for that better world, and that if those plans are to be ready in time they must be made now. The proposals are a sign of the belief that the object of government in peace and in war is the happiness of the common man.

"Freedom from want," concludes the report, "cannot be forced on a democracy or given to a democracy. It must be won by them. Winning it needs courage and faith and a sense of national unity; courage to face facts and difficulties and overcome them; faith in our future and in the ideals of fair-play and freedom for which century after century our forefathers were prepared to die; a sense of national unity overriding the interests of any class or section."

ORIGIN OF THE CORONIUM LINES

By Dr. A. HUNTER

IT is now nearly three quarters of a century since the green line in the spectrum of the solar corona was first observed. Subsequent observations—few eclipse expeditions since then have neglected this field of study—have established that the inner corona emits a spectrum consisting of at least twenty-two broad bright lines superposed on a continuum. The brightest line is usually the green one at 5303 A., but considerable variations in the relative intensity of the lines are found from eclipse to eclipse, and recent coronagraph observations made without an eclipse confirm large day-to-day intensity variations. None of the lines have ever been produced in the laboratory, nor indeed have they ever been observed in any other celestial source, except for a brief appearance during a nova-like outburst by the variable star *RS* Ophiuchi in 1933. There has been no lack of suggestions regarding their origin: they have been attributed in turn to iron, to 'proto-fluorine', to singly- and doubly-ionized calcium, to argon, and to oxygen, neutral and ionized; all with a certain amount of supporting evidence, and the last three within the past fifteen years. None of these assignments has had general support, however, because none of them explains more than a small selection of the facts.

Early attacks on the problem of identification proceeded along the only lines then possible, namely, by seeking wave-length coincidences with known spectra. Many such identifications announced in the days of visual observations did not survive the stricter tests applied when photography made fairly accurate wave-lengths available. By the turn of the century it was decided that even the closer coincidences were due to chance, and that the mysterious lines could not be attributed to any known element. At this stage the emitting substance was named 'coronium', and the possibility that it was indeed a new chemical element was seriously discussed. After all, was there not a renowned precedent for such a discovery in the observation of helium on the sun nearly thirty years before its detection on the earth? With the gradual filling of the Periodic Table, however, this possibility grew less and less likely. The discovery which was perhaps its death-blow came in 1935 when 'nebulium', the hypothetical element responsible for a somewhat similar spectrum emitted by the gaseous nebulæ, was identified by Bowen in unexceptionable fashion as a mixture of ionized oxygen and nitrogen. After this it was accepted that coronium must be a familiar substance excited by some process which develops the coronal spectrum while completely suppressing the normal one.

The most hopeful line of attack when direct comparison with known spectra failed was to examine intercombinations between known term values; that is, to compare the observed frequencies of the coronal radiation with the frequency differences between known energy levels of likely atoms or ions. The transitions involved would probably be 'forbidden' (as in nebulium) or at any rate of low probability, otherwise they would have been observed in terrestrial sources; but this need not hamper the search, since the energy levels concerned may be known quite accurately from permitted transitions which involve them. The energy diagrams of many neutral atoms were already quite well known; well enough to decide forthwith that they would indicate only what coronium was not, not what it was. The next step was to extend the search to ionized atoms. In the past fifteen years the growth of our spectroscopic knowledge of these has made possible a systematic survey of the metastable states of ions which are likely to occur in the corona. The forbidden lines, with some of which, it was hoped, the coronal lines would be identified, are inward transitions from these metastable states, transitions which do not take place in normal conditions of excitation. Metastability will be favoured by the low pressure known to exist in the outer regions of the sun's atmosphere; in these conditions an atom, once it reaches a metastable state, will remain there long enough to get rid of its excess energy by a forbidden radiative transition rather than by a collision. But when some five years ago patient search among the forbidden lines to be expected in such ions as Fe II, Fe III, Ca II, Ti II, Ti III, A II and many others had failed to give any coincidences with the observed coronal lines, hope began to fade. It was pointed out that before the metastable ions could emit forbidden lines, the intense solar radiation permeating the corona should raise them to normal states, from which allowed transitions would give rise to the ordinary spectral lines of the elements concerned. That this widely accepted objection is not necessarily valid, however, and that the method of attack was probably on the right lines, will appear later.

At this stage opinion veered to the opposite extreme. Emphasis was placed on the great width of the coronal lines, which is not by any means a feature of the nebular lines identified with such success as forbidden lines. Line-widths of the order of angstroms indicate that the excited states involved have unusually short lifetimes—quite the reverse of metastability. It was accordingly suggested that double-electron excitation is occurring in the atom or atoms concerned. In this process, an electron belonging to the inner core, which remains undisturbed in the ordinary way, is removed to an outer orbit at the same time as an outer electron is excited. With different excitations of the outer electron the atom will be in energy states from which it can radiate a new series of lines quite different from its ordinary spectrum. In many of these states it possesses more than its ionization energy; its lifetime in such levels will be short, because spontaneous ionization converting it to a normal ion and an electron with kinetic energy will in general be possible. The probability of this auto-ionization at any level will determine the width of a line originating in that level.

Between 1933 and 1935 wide lines due to such inner-electron excitation were observed in the laboratory in the alkali metals, in zinc, cadmium and mercury, and in the rare gases. The temptation to draw an astrophysical parallel was strong, and in 1934 it was predicted[1] that this type of excitation in helium—a likely atom, since helium and coronium are known to co-exist in the upper chromosphere—will produce several diffuse lines in the visible region of the spectrum. Unfortunately, attempts[2] to produce the coronal lines in helium in the laboratory under conditions likely to favour two-electron excitation have not had the success which attended, for example, McLennan's search for the auroral green line in oxygen. The absence of ordinary helium lines from the coronal spectrum is also a troublesome point with this hypothesis. What is more disturbing, however, is that the great line-breadths, which are fundamental in the theory, may not be intrinsic at all: they could be due to some secondary process occurring after the emission of the lines. Turbulence will broaden the lines by the Doppler effect, for example, and Doppler broadening is particularly likely, for the equivalent widths of the lines are roughly proportional to their wave-lengths. It is significant here that velocities of 10 km./sec. in coronal arcs have been observed directly by Waldmeier[3] with the Arosa coronagraph; an average turbulent velocity of this order would widen lines, initially quite sharp, by nearly the required amount.

At the beginning of the War, then, the problem of the source of the coronal lines seemed little nearer solution than it was a decade before; and it looked as if this long-standing challenge to spectroscopists and astrophysicists would remain in abeyance until such problems could again be attacked. In a short paper[4] which has just reached Great Britain from Sweden, however, B. Edlén proposes a solution which is by far the most attractive yet put forward and which will command widespread support. His method is not different in essentials from the one outlined above, in which the emission is attributed to forbidden transitions from metastable states of ionized atoms; but he abandons the somewhat conservative approach hitherto adopted and boldly examines the metastable levels of atoms which have lost from nine to fifteen electrons. Matter in this high state of ionization can be produced in the laboratory by passing high-energy sparks between metal electrodes, the ionization stage being roughly controllable by varying the capacity and inductance of the electric circuit and the potential across the spark gap. High-capacity condensers ($\sim 0{\cdot}5\mu$F.) charged to 100,000 volts have been used for extreme excitation of this sort. The development of vacuum spectrographs using diffraction gratings at grazing incidence has made it possible to photograph the spectra of these ions, the ultimate lines of which lie so far in the extreme ultra-violet as to merit the description of soft X-rays rather than of optical radiation.

Analysis of the spectra so produced has been very largely due to Edlén, working in Prof. Siegbahn's laboratory at Uppsala, and this is by no means the first time that results of interest and importance to astronomy have followed from his work. In this connexion it is relevant to recall that in collaboration with Bowen he recently identified[5] nine lines in the spectrum of Nova Pictoris with forbidden transitions in Fe VII. He now attributes practically the whole of the coronal line spectrum to forbidden transitions in calcium (Ca XII and Ca XIII), nickel (Ni XII, Ni XIII, Ni XV, Ni XVI), and, especially, iron (Fe X, Fe XI, Fe XIII, Fe XIV).

Wave-length (A.)	Intensity		Identification		Ionization potental (eV.)
	Grotrian	Lyot	Ion	Transition	
3328·1	1·0		Ca XII	$^2P_{3/2}-^2P_{1/2}$	589
3388·10	16		Fe XIII	$^3P_2-^1D_2$	325
3454·13	2·3				
3600·97	2·1		Ni XVI	$^2P_{1/2}-^2P_{3/2}$	455
3642·87			Ni XIII	$^3P_1-^1D_2$	350
3800·77					
3986·88	0·7		Fe XI	$^3P_1-^1D_2$	261
4086·29	1·0		Ca XIII	$^3P_2-^3P_1$	655
4231·4	2·6		Ni XII	$^2P_{3/2}-^2P_{1/2}$	318
4311·5					
4359					
4567	1·1				
5116·03	4·3	2·6	Ni XIII	$^3P_2-^3P_1$	350
5302·86	100	120	Fe XIV	$^2P_{1/2}-^2P_{3/2}$	355
5694·42		1·5			
6374·51	8·1	28	Fe X	$^2P_{3/2}-^2P_{1/2}$	233
6701·83	5·4	3·3	Ni XV	$^3P_0-^3P_1$	422
7059·62		4			
7891·94		29	Fe XI	$^3P_2-^3P_1$	261
8024·21		1·3	Ni XV	$^3P_1-^3P_2$	422
10746·80		240	Fe XIII	$^3P_0-^3P_1$	325
10797·95		150	Fe XIII	$^3P_1-^3P_2$	325

An observation by Grotrian[6] that the wave-numbers of the coronal lines at 6374 A. and 7892 A. coincide with the doublet separations in the ground terms of Fe X and Fe XI first suggested to Edlén a search for analogous term separations in other ions. This led immediately to the discovery that two other strong lines coincide with the corresponding term separations in Ca XII and Ca XIII (see the accompanying table, which is taken from Edlén's paper). No other coincidences with known term differences have been found (largely, no doubt, because the spectra of atoms in such high stages of ionization are as yet very imperfectly analysed), but this early success in classifying four strong coronal lines can scarcely be due to chance. This being so, Edlén proceeds on the assumption that the whole coronal spectrum consists of forbidden lines of atoms in higher stages of ionization than have hitherto been considered. Enough is known from his own work on the extreme ultra-violet spectra of vacuum sparks to make it possible to extrapolate with reasonable accuracy along iso-electronic sequences, and so to obtain estimated term separations in ions for which term analyses are imperfect or even lacking altogether. Judging by the intensity of Fe X and Fe XI, he argues, iron is apparently present in abundance; yet the Nova Pictoris lines of Fe VII are not present in the corona. The reason for their absence is suggested by the presence of Ca XII and Ca XIII: evidently the excitation level in the corona is too high for Fe VII to appear. This immediately suggests a search for Fe XII, Fe XIII, Fe XIV, Fe XV, Fe XVI and Fe XVII. Examining these, he finds that the extrapolated term-differences in the first ion are not observable astronomically, while the last three have no deep metastable levels. This leaves Fe XIII and Fe XIV, and it is of great significance that the extrapolated ground-doublet separation in Fe XIV points unmistakably to the famous green line at 5303 A., while the next strongest lines, including the infra-red ones discovered by Lyot, correspond to the Fe XIII transitions given in the table. These identifications with term differences in iron atoms from which 9, 10, 12 and 13 electrons have been removed dispose of more than 90 per cent of the coronal emission, when the line intensities are taken into account.

On the assumption that these classifications are correct, we are now on firm enough ground to extrapolate further to elements close to iron in the Periodic Table. Examination of the iso-electronic ions of nickel shows that analogues of all except one of the transitions already identified in iron appear among the observed coronal lines; and the missing nickel line is not in the accessible wave-length range. This accounts for six more lines, the intensities of which are roughly one-tenth that of the corresponding iron lines; this ratio agrees well with the usual relative cosmic abundance of these elements. Thus all except about three per cent of the coronal line emission can be attributed to forbidden transitions in highly ionized calcium, iron and nickel.

It is encouraging that the proposed identifications classify the various lines in a way which agrees well with Lyot's grouping of the coronal lines by their intensity distribution round the sun. In particular, the marked differences in physical behaviour pointed out by Waldmeier between the green line at 5303 A. and the red one at 6374 A. are no doubt connected with the very different excitation needed for the production of the two lines. It is important, of course, to examine the problem of coronal emission as a whole, and not to be content with a series of positive identifications, however satisfactory. What of other constituents of the sun's outer atmosphere ? Atoms of potassium, chromium, manganese and cobalt, which have strong lines in the ordinary solar spectrum, might be expected to show some evidence of their existence in the corona, since observable lines are predicted in the spectra of their ions at the appropriate ionization level. That they do not is attributed by Edlén to low abundance in the corona ; and he makes the suggestive remark that meteoritic matter is rich in iron and nickel (in about the abundance ratio suggested by the relative strengths of their lines) but not in potassium, chromium, manganese or cobalt. All the other elements well represented in meteorites (oxygen, magnesium, aluminium, silicon and sulphur) have ions which do not give rise to strong lines in the observable range.

Turning now to the physical conditions required by Edlén's proposals, the most striking fact is the enormous energy required to strip the atoms of iron, nickel and calcium of so many electrons. In this connexion it is perhaps significant that Lyot, in order to account for the width of the coronal lines by pure thermal motion, found that a temperature of 660,000° K. would be needed if the emitting particles were as heavy as oxygen atoms. Recalculating to iron atoms, 3·5 times heavier, a coronal temperature of 2,300,000° K. must be postulated ; and at this temperature an atom in thermal equilibrium with its neighbours will have an average translational energy of more than 300 electron volts. What may be the physical meaning of a coronal 'temperature' of more than two million degrees is as yet unknown, but it may be recalled that many solar and extra-solar phenomena demand excitation far higher than that provided by total radiation of 6,000° K. quality. The excitation of hydrogen and especially of helium in the chromosphere and prominences, the production of the 'twilight flash' spectrum of $N_2{}^+$ in the earth's upper atmosphere, the ionization of carbon monoxide and nitrogen molecules in comet tails by solar radiation, and the production of *D*-region ionization in the ionosphere by bright eruptions on the sun may all be classed as super-excitation processes indicating solar 'temperatures' ranging from 10,000° K. to 20,000° K. in the ultra-violet.

No other known phenomenon, however, requires such a tremendous input of energy to the atoms in the solar neighbourhood as Edlén's proposed mechanism, though of course this is not an argument against the validity of his theory. The objection originally raised to hypotheses of this type, namely, that metastable atomic states cannot persist long enough in an intense radiation field to give rise to forbidden lines, cannot be urged against the new identifications, for the ultimate absorption lines of these highly ionized atoms are in the soft X-ray region, where presumably the sun does not emit a great deal of radiation. The particles will therefore be as little disturbed by radiation as by collision, and can emit lines which are normally forbidden. A point in favour of the theory is that it accounts for the presence in the inner corona of large numbers of free electrons, which will scatter sunlight and so give rise to the faint continuous background of the emission lines.

A difficulty is encountered, however, if the doubling observed in 5303 A. by Waldmeier[8] is really due, as he suggests, to self-reversal. In this process, a narrow absorption line is superposed on a broad emission line, thus producing an apparently double line. The phenomenon is of common occurrence in certain sources such as laboratory arcs and the sun itself, where hot emitting particles are surrounded by an envelope consisting of similar but cooler particles. But not all lines can show self-absorption, and we know of no physical conditions compatible with those likely to exist in the corona which can produce absorption of forbidden lines. The difficulty is not insuperable, however, since other causes can produce doubling of lines ; the need now is for more observations to distinguish between the various possibilities.

Qualitative support is lent to the new theory by certain observations of novæ. In these objects an outburst of energy is believed to be followed by the ejection of a shell or a series of shells of matter, the central star being soon surrounded by an extended low-pressure atmosphere which might on general grounds be expected to behave rather as the solar corona does. It is thus significant that, as mentioned above, forbidden lines of Fe VII have been identified with certainty in the spectrum of Nova Pictoris, and that some of the coronal lines themselves have appeared in Nova Ophiuchi. That the coronal spectrum is such a relatively inconspicuous part of the radiation emitted by the sun, whereas forbidden lines are often very prominent in nova spectra, is thus probably a difference of degree rather than of kind. We can never hope to detect the coronal spectra of other stars unless their envelopes become major structural features by some such outburst as this. The important point is that the coronal lines are produced in conditions which favour the emission of forbidden lines in highly ionized iron.

The future of the theory, it may be surmised, lies partly in laboratory experiment and partly in astronomical observation. While only four lines can be described as directly identified, the theory can scarcely be regarded as established, especially when it is remembered that there is an inevitable loss of precision in working from short-wave measurements through frequency differences to wave-lengths in the visible region. However, the number of well-established term analyses of highly ionized atoms is already considerable, and it is unlikely that Edlén's extrapolations are too daring, though unfortunately he gives no estimate of his error of prediction. What is needed now is a thorough analysis of the ultra-violet spectra of Fe XIII, Fe XIV, Ni XV, and Ni XVI. It is most unlikely that the coronal lines can yet be reproduced in the laboratory, since to keep these stripped atoms in metastable states for times of the order of a second is quite beyond our present technique ; but a definitive energy-level analysis obtained from the permitted ultra-violet lines would provide conclusive evidence and should not prove impossible with present means of attack. Meanwhile, coronagraph observations such as those projected by Lyot and Waldmeier will give valuable auxiliary information ; and a critical re-examination of past eclipse spectrograms, carried out in the light of their recent results, would probably be extremely useful.

On the theoretical side the position is rather different. Here it must be admitted that the new suggestions are in advance of solar physics. But their somewhat startling nature need occasion no surprise: other suggestions along more conservative lines have been so thoroughly explored that something out of the ordinary was to be expected. The immediate reaction of most astronomers will no doubt be one of incredulity that such highly ionized matter as Edlén's proposals call for should exist in the outer envelope of a relatively cool star like the sun. But this is not altogether a valid objection: if the lines can be satisfactorily identified, then our ideas concerning the conditions existing in the solar corona must be modified. Twenty years work has been done on this problem by physicists whose horizon has been tacitly limited by the astronomers' conception of coronal conditions; if, where they have failed, a solution which ignores this conception proves otherwise acceptable, then astronomers will welcome the opportunity of enlarging their ideas, and solar physics will benefit accordingly.

THE HONEYBEE

By C. G. BUTLER
Rothamsted Experimental Station

FROM the beekeeper's point of view, honey production is the main object of beekeeping; but from the national point of view it is only a by-product. Both in peace and war, the chief contribution of beekeeping to the national economy is the provision of pollinators for crops such as fruit, clover and mustard. Except for this fact it is doubtful whether the allocation of 15–20 lb. of sugar per annum to each colony could be justified, even though in an average season an average surplus of 30–35 lb. of sugar (as 'honey-sugar') should be obtained over and above the 20–25 lb. of honey which should be left in the hive in the autumn for the use of the bees during the non-productive months of the year. Recent estimates show there to be nearly 56,000 beekeepers, owning a total of about 430,000 colonies of bees, in England and Wales alone, but the allocation of some three or four thousand tons of sugar to them annually is a small price to pay for successful fruit and seed crops.

At a symposium on the honeybee organized by the Association of Applied Biologists, on December 4[1], Mr. C. G. Butler showed figures indicating that in such cold spring weather as that of 1941, honeybees were almost the only pollinating insects present in orchards in which comparative counts of pollinating insects were made, and the view was expressed that they were responsible for a high proportion of the fruit set. It was further pointed out that there is good evidence that in those areas where large orchards and acreages of seed crops are being grown there are often insufficient wild pollinating insects present for full production to be obtained. Quite apart from this crowding effect of crops upsetting the natural balance between pollinators and flowers requiring pollination, intensive cultivation has resulted in destruction of the nests and habitats of many wild pollinating insects.

It is greatly to be regretted that British growers have not yet fully realized the value of honeybees as pollinators the numbers and location of which can readily be controlled. Many countries are much more advanced in this respect and recognize that the honeybee is almost certainly the most important pollinating insect.

The small 'back-yard' beekeepers, scattered throughout the length and breadth of Britain, play a most important part in providing the necessary pollinating insects. There is no evidence, however, of any marked concentration of beekeeping in the predominantly fruit-growing areas.

It has recently been estimated that the approximate cash value of the honeybee to the nation as a pollinator of fruit crops alone is £4,000,000 per annum, and an average of about £1,250,000 worth of honey is produced annually.

In order to make the best use of honeybees for the pollination both of hard and soft fruit and of many important seed crops, the bees must be well kept and healthy, and suitably managed and placed for the crop in question.

A recent survey was designed to discover the distribution of diseases of the adult bee, particularly with respect to acarine disease, the complaint which was almost certainly largely responsible for the extermination of more than 90 per cent of all the colonies of honeybees in Britain about the time of the War of 1914–18. The results show that it is a fair assumption that at least one colony in every five in England and Wales was suffering from this complaint last winter. Steps are now being taken to make beekeepers more 'disease conscious'. Since satisfactory treatment for acarine disease is now known there is no reason why this complaint should not be brought under control.

The position with regard to other diseases of the adult bee is not nearly so serious in Great Britain, although such diseases are only too prevalent on the Continent.

The other diseases of the honeybee which are a serious cause of concern at the present time are two diseases of the brood, European and American foul brood, usually known collectively as foul brood. Of these the commoner is American foul brood caused by the bacterium, *Bacillus larvæ*. This disease is both widespread and common in England and Wales. No cure, in the true sense of the word, is known for either of the kinds of foul brood, but American foul brood can be eliminated from a colony by the careful use of methods designed to separate the bees from their brood and honey. Such methods, however, require extremely careful application and, for this reason, as pointed out by Mr. P. S. Milne, should only be applied to strong colonies which are really worth saving, and then only under the supervision of experts. A great deal of valuable work in combating foul brood has been carried out by Bee Disease Insurance, Ltd., which is operated as a 'friendly society', but experience has shown that there are a small number of cases of foul brood which, on account of apathy or selfishness on the part of the owners of the apiaries concerned, could not be reached by any voluntary organization. The Foul Brood Disease of Bees Order, 1942, was put into operation in March 1942 in order to deal with those cases where a beekeeper whose apiary is believed to be serving as a potential source of infection refuses to co-operate with any such voluntary organization. During its first season of operation several hundred cases have been dealt with under the Order.

Concurrent with the gradual realization of the value of the honeybee as a pollinator and its use for this purpose in many orchards, complaints of the poisoning of honeybees by insecticidal and fungicidal sprays have increased. Despite certain ill-informed statements in the Press, spray poisoning of honeybees in Great Britain is in no way comparable with the position in certain States in America, but the matter is sufficiently serious to warrant careful investigation.

As pointed out by Mr. G. A. Carter, the ingredient in the more usual spray mixtures which has been found to cause poisoning of honeybees is lead, or calcium, arsenate; the small dose of 0·00005 mgm. of arsenic being sufficient to kill a bee. This substance, contrary to statements sometimes made, is no more attractive to the honeybee than distilled water, and is only taken by the honeybee by accident either when seeking water from the foliage and trunks of sprayed trees or when collecting pollen from flowers, either from the trees themselves or from weeds growing near the trees on to which the spray has drifted. Only some ten or a dozen apiaries have been reported as being affected in each of the last three years, although it should be noted that detection is not simple since, when poisoning from drip water occurs, the majority of the foraging bees die in the field. Only when contaminated pollen is collected is serious poisoning of the brood likely to occur. The spraying of open blossom with washes containing arsenic should be avoided whenever possible. Not only does such poisoning harm the beekeeper but also, since about 90 per cent of the bees working an orchard are on the trees at any given time on a good flying day, the grower is likely to lose a high proportion of his pollinating insects immediately.

The use of deterrents to keep bees away from arsenical washes is receiving consideration in the Bee Research Laboratory at Rothamsted Experimental Station. In laboratory trials, discussed by Mr. D. J. Finney, lime-sulphur and nicotine sulphate in the strengths usually employed in spray mixtures both acted as strong repellents to the honeybee, provided an adequate source of uncontaminated food was present at the same time. This suggests that compound sprays incorporating these substances are not very likely to cause poisoning of honeybees in the field, provided that sprays are not applied to open blossom. No absolute deterrent has so far been discovered and the spraying of open blossom with arsenical sprays, even though they contain lime-sulphur or nicotine sulphate, is likely to harm bees.

The observation of Minderhoud that a foraging honeybee confines its attention to a relatively small area, usually 4–5 yards in diameter, of a crop in which nectar is abundant, has been confirmed by Messrs. Butler, Jeffree and Kalmus at Rothamsted Experimental Station. The honeybee does not wander over a crop at random. However, if a sufficient force of field bees is present, a population of wandering bees is superimposed upon this fixed population. It can be shown that this wandering population is composed of a few old bees driven on by competition and of a large number of young bees which have not yet become fixed to any particular area of the crop in question.

It is this wandering population, superimposed upon the fixed population, which is of value to the fruit-grower in obtaining cross-pollination of his trees; and it appears probable that many of the cases of apparent failure to increase crops by the use of honeybees as pollinating agents is attributable to the use of an insufficient force of field bees. It is suggested that the force required can be determined over a number of years by placing the pollinating colonies together in the centre of the orchard concerned and noting the set of fruit. If an insufficient force of bees is present, other things being equal, the greatest set will be found near the hives and will decrease progressively outside this zone of competition. When an even set of fruit has been obtained throughout the orchard the force of bees is probably correct. Competition between trees and weeds must also be avoided. In many plum orchards dandelions and other weeds produce such competition, and cause neglect of the trees in favour of the weeds.

The problem of the producer of pure seed is somewhat different from that of the fruit-grower, but here again appreciation and application of the principles involved in the use of honeybees as pollinating agents will in many cases lead to increased yields.

The factors which control the behaviour of the honeybee in the field are extremely complicated and often mutually interdependent, but the elaboration of such a bee-counter[2] as described by Dr. A. C. Fabergé will materially assist in the elucidation of these problems, to the benefit of both the beekeeper and the grower.

A METHOD OF PHYSIOLOGICAL ASSAY OF PYRETHRUM EXTRACTS

By Dr. OTTO LOWENSTEIN

Department of Zoology, University of Glasgow

THE need for economy in the use of pyrethrum extracts in insecticidal practice makes necessary the continuous search for substitute toxic agents or at least for activator substances which may be added to pyrethrin mixtures as adjuvants to raise their effectiveness and thus cut down the consumption of pyrethrin. Parkin[1] published in NATURE the description of a method of biological assay of pyrethrin sprays in which the test insects (*Tribolium castaneum*), bred and kept under rigidly controlled conditions, are exposed by means of a standard method of application to various concentrations of pyrethrum extract in heavy oil. This method yields a reliable discrimination between the toxic effect of two solutions differing by 0·1 per cent in their content of pyrethrin I, which amounts roughly to a difference of 0·2 per cent in their total pyrethrin content. According to Parkin, careful organization of a steady supply of insects from controlled stocks is one of the factors essential for the practical success of this method of assay.

It is obvious that the amount of such insects available might easily become a bottleneck, whenever a greater number of substances in various combinations have to be tested for their toxicity. A method that would allow the carrying out of rapid preliminary tests and at the same time yield a fairly high degree of accurate indication of the relative effectiveness of pyrethrin preparations of various compositions and strengths, without necessitating the use of such valuable insect material, should therefore prove very useful.

During physiological investigations into the nature of the action of pyrethrin on the insect nervous system, a method was worked out which might serve this purpose. This method is based on the observation and recording of action potentials in the exposed abdominal nerve cord of *Blatta orientalis*, by means of a standard resistance capacity coupled amplifier in conjunction with an oscillograph and a loudspeaker. A detailed account of the method and the results of the physiological investigation will be published elsewhere. In the present article it may suffice to give the following outline of the experimental procedure. The abdomen of an adult female cockroach is severed from the thorax and pinned down ventral side upwards on a piece of cork. A median strip of the body wall is then cut out, deflected backwards, and pinned down as shown in Fig. 1. The ventral nerve cord is thus fully exposed for the insertion of the recording electrodes and for the application of the pyrethrum extract to be tested. The grid electrode is placed on the 5th abdominal ganglion, the neutral electrode rests on a pad of cotton wool soaked with saline which is in contact with the abdominal tissues. The electrodes are mounted in a metal screen box connected to earth, protecting the preparation from outside electrical interference during observation.

Of the various types of action potentials that can be recorded from such a preparation, one is of particular importance for the present purpose, since it is easily recognizable by the typical sound it produces in the loudspeaker, and because its disappearance under the influence of pyrethrin furnishes a clear end point, which can serve as a criterion for the speed of action of the toxic agent under observation. The potential in question arises in so-called giant-fibre neurons, situated in the 6th abdominal ganglion, which make synaptic connexion with afferent sensory fibres from the hair sensillæ on the cerci and which send giant fibre pathways forward into the central nervous system[2]. The potentials are of relatively high amplitude and arise whenever the hair sensillæ on the cerci are stimulated by a puff of air directed against the cerci. Fig. 2 shows an oscillographic record of the effect of such cercal stimulation. The high amplitude spikes represent the above described giant-fibre discharge. An unmistakable series of crackling reports can be heard in the loudspeaker whenever such giant-fibre potentials arise in the cord. The acoustical recognition is so easy that the use of oscillograph and camera can be dispensed with in actual practice. The cerci can easily be stimulated by gently blowing against them.

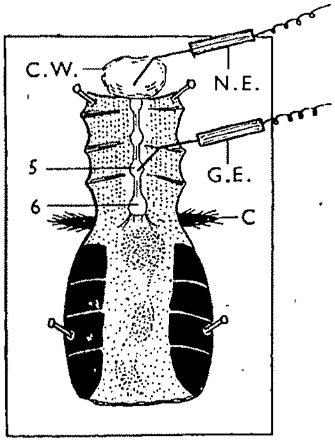

Fig. 1. Exposed ventral nerve cord of *Blatta orientalis*. *C.*, cercus; *C.W.*, pad of cotton wool; *G.E.*, grid electrode; *N.E.*, neutral electrode; 5 and 6, fifth and sixth abdominal ganglions.

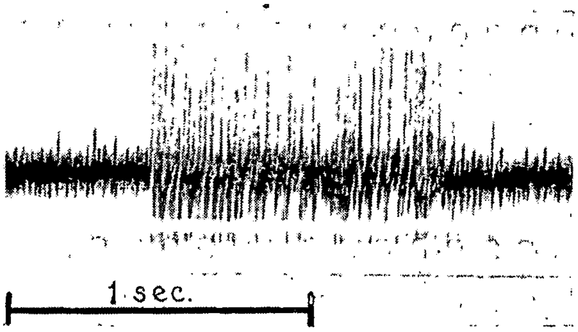

Fig. 2. Oscillograph record of giant-fibre response to stimulation of cercal hair-sensillæ.

Under the influence of pyrethrin a strict sequence of pathological events occurs. After an initial excitatory phase, marked by a massive discharge of a number of types of impulses, a spontaneous synchronized discharge of continuous trains of giant-fibre potentials becomes prominent. After this the response of giant-fibre neurons to sensory stimulation becomes abnormal in various ways and at last fails completely to occur. The disappearance of this response heralds the final decay of the electrical activity of the preparation. The time taken from the moment of application of the insecticide to the disappearance of the giant-fibre response shows a clear dependence on the concentration of the pyrethrum extract used.

This is borne out by the result of seventy experiments in which solutions of 0·07, 0·13, 0·23, 0·33, 0·65, 0·95, 1·3 per cent total pyrethrins in heavy oil were applied, ten experiments being carried out with each of these concentrations. At one minute intervals after application of the insecticide the preparation was stimulated via the cerci to test for the presence of the giant-fibre response. The experiments were continued until the giant-fibre response had finally disappeared. The time of observation was restricted to a maximum of one hour, in order to exclude any interference by pathological effects other than those caused by the insecticide.

The accompanying table shows the mean survival times of the giant-fibre response found for each group of ten experiments at 19–20° C. Plotted

% total pyrethrins	Mean survival time of giant-fibre response (min.) at 19–20° C.
0·07	>45·5*
0·13	26·8 ± 7·1
0·23	4·7 ± 1·0
0·33	2·3 ± 0·6
0·65	2·2 ± 0·8
0·95	1·7 ± 0·5
1·30	0·6 ± 0·2

* In five out of the ten experiments with this concentration the survival time of the giant-fibre response exceeded 60 min., the maximum time of observation.

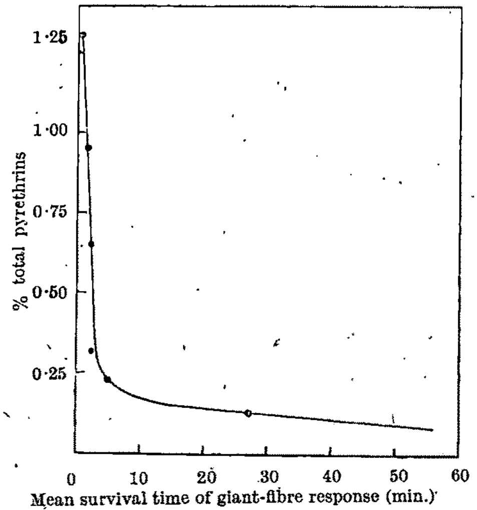

Fig. 3. TIME-CONCENTRATION CURVE (EXPLANATION IN TEXT).

against concentrations, these values yield a hyperbolic time-concentration curve shown in Fig. 3. As can be seen from the magnitude of the standard error of the mean values there is a considerable scatter of the individual readings within each group. This is only to be expected in view of the fact that the experimental animals were obtained by trapping in various localities, and differed not only in size and age but also in other respects, such as amount of fat body, hydration of tissues, etc. A further factor responsible for such variations in 'survival time' is the difficulty in the application of a standard amount of insecticide. The solutions were applied freely all over the exposed tissues of the preparation by means of a No. 1 water-colour brush, every care having been taken that no part of the ventral nerve cord was left protected by remnants of fat body. Differences in the amount of body fluid present, however, can have quite a decided effect on the speed of penetration of the oily pyrethrin solutions into the nervous tissues.

The discriminating power of this method is fairly poor for concentrations above 0·33 per cent total pyrethrins, a concentration which seems to represent an upper limit above which an increase in pyrethrin content does not proportionally hasten the drug's toxic effect on the exposed nervous system. The observed mean difference in survival time for 0·23 per cent and 0·13 per cent solutions is, however, of a completely satisfactory statistical significance. At this point of the range of concentrations the method is most sensitive, and the clear discrimination between the physiological effects of two solutions differing by only 0·1 per cent in their total pyrethrin content compares quite favourably with the maximum sensitivity to a difference of 0·2 per cent total pyrethrins yielded by the method of biological assay described by Parkin[1]. The fact that the physiological method of assay here described is most sensitive near the lower end of the scale of concentrations is a necessary consequence of the direct application of the insecticide to the exposed nervous tissues. For intact insects a comparable critical range of concentrations seems to lie in the neighbourhood of 1·6 per cent or 1·3 per cent total pyrethrin content. This factor has to be taken into account in comparing the results gained by the two different methods of assay. It is tentatively suggested that there is an approximate correspondence in toxic effect between a 1·6 per cent pyrethrin solution when applied externally, and a 0·3 per cent solution of the same composition on direct application to the exposed nervous system.

The advantages of the physiological method, which, apart from its usefulness in qualitative tests, appears to be especially suitable for the preliminary quantitative assay of relative toxicities, may be summed up as follows:

(1) The test animals (cockroaches) are easily obtainable and ten animals only are necessary for each test. More valuable insect material can thus be saved for a small number of final 'biological' tests.

(2) The exposure of the nervous system does not represent any technical difficulty; the preparation can be mounted for electrical observation within two to three minutes from the beginning of the dissection, and the ten experiments necessary for each test can be completed in a maximum time of 5–8 hours.

(3) The sensitivity of the method is unexpectedly satisfactory, considering the variability and relatively small number of test insects used.

(4) The fact that acoustical diagnosis is completely sufficient to furnish a satisfactory end point at low amplification renders the use of a costly oscillograph and recording camera unnecessary. The apparatus need therefore only consist of a standard 3–4-valve resistance capacity coupled amplifier in conjunction with a one-valve power stage and a loudspeaker.

(5) The experimental procedure as adapted for practical testing is sufficiently simple to be carried out in a routine way by any trained biologist. It does not call for specialized experience in electrophysiology.

OBITUARIES

Mr. M. P. J. Swift, and Mr. M. J. Swift

THE name of Swift has been associated with the manufacture of scientific instruments since the inception of this firm in 1852, and has been a household word whenever microscopes have been mentioned. By the death of Mansell Powell John Swift on October 12, 1942, at the age of fifty-seven, the firm has lost one of its outstanding figures. M. P. J. Swift was educated at University College School, London, and entered the firm when he was eighteen. He did much towards raising the microscope to its present high standard of precision, especially by attention to detail both in its optical and mechanical requirements. His interest in the development of the polarization microscope was well known, and the various optical accessories connected with this branch of work (for example, Nicol, Glan-Thompson prisms, retardation wedges, etc.), always difficult to make, held a peculiar attraction for him. His energy, enthusiasm, and thoroughness in all he undertook was maintained to the end: a most likable man, who will be greatly missed by all who knew him.

By a strange coincidence, Mansell James Swift, father of M. P. J. Swift, died within one day of his son, namely, on October 13, at the age of eighty-eight. He was apprenticed to his father James Powell Swift (1826–1906), who founded the original firm, and who himself served as an apprentice with Messrs. Ross, Ltd. He was a fellow of the Royal Microscopical Society for thirty-six years.

The interest in scientific and optical instruments displayed by the three members of the firm mentioned above goes back yet one more generation. Thomas Swift (1799–1882), father of James Powell Swift, although at one time a hosier in Fenchurch Street, London, was sufficiently interested in scientific instruments to open such a business in Bendigo, Australia, where many microscopes were sent out to him by his son.

With such a background, the name of Swift will doubtless continue to be associated with optical instruments and microscopes of high quality.

B. K. JOHNSON.

NEWS and VIEWS

Prof. D. B. McQuistan

PROF. D. B. MCQUISTAN, who recently retired from the Freeland chair of natural philosophy in the Royal Technical College, Glasgow, has now, through failing health, been forced to relinquish a lifetime devoted to the cause of education. A brilliant student of the University of Glasgow, he was awarded the Thomas Logan Memorial Medal and Prize for the most distinguished graduate in arts of his year, with first-class honours in mathematics and natural philosophy, and in classics. The William Houldsworth research studentship afforded him the opportunity of spending a profitable year at the University of Cambridge, and, along with his later services as a mathematical teacher, he was well equipped for the duties of the chair which he afterwards occupied with great distinction. Many thousands of students will remember with gratitude his lucidity as a lecturer, and his exceptional aptitude in clarifying any difficult mathematical or scientific complexity. His popular lectures of scientific interest to varied audiences were an inspiration to the expert and a delight to the novice.

We regret to announce that it will no longer be possible, on account of the limited supply of copies of NATURE available, to give authors of "Letters to the Editors" more than one copy of an issue in which their contribution appears.

On his retiral, Prof. McQuistan was chairman of the Board of Studies at the Royal Technical College, and for many years he did invaluable and onerous work as convener of the Business Committee of the General Council of the University of Glasgow. His colleagues in the Dumbartonshire Education Authority will undoubtedly miss his unfailing and ungrudging service. His logical mind and calm temperament were always conducive to wise decisions. With unerring instinct he foresaw the possibilities of the film as an aid to education, and was convener of the Advisory Committee on the Production of Educational Films, under the auspices of the Scottish Film Council. Prof. McQuistan's present absence from active participation in educational matters creates a void, and his many acquaintances will cherish his great teaching qualities, his brilliant intellect, and, above all, his charming and lovable personality.

Ignaz von Born

ON December 26 occurs the bicentenary of the birth of Ignaz von Born, one of the first to realize the great part fossils were to play in historical geology and the first to describe the use of mercury in the extraction of gold and silver. Born at Carlsburg in Transylvania, he was educated at Hermannstadt and Vienna, and studied law at Prague. He then made a journey through Germany, Holland and France studying the minerals, mining, etc., and a year or two later made another mineralogical journey through Hungary and Transylvania. An account of this second journey, in the form of letters, was published in 1774 by the Swedish mineralogist, J. J. Ferber (1743–90). At Prague, where he held a post as mining councillor, Born assisted in forming a scientific society. In 1776 he was called to Vienna by the Empress Maria Theresa to arrange the natural history collections, which he afterwards described in a fine work. He continued to reside at Vienna until his death on July 24, 1791. One of the last of his books was his "New Process of Amalgamation of Gold and Silver Ores . . ."

Born's "Travels through the Banat of Termeswar, Transylvania and Hungary" and his book on "Amalgamation" were translated into English by a clever but unscrupulous German, Prof. Rudolf Erich Raspe (1737–94), who after stealing coins from the collections at Cassel fled to England, where he was already a foreign member of the Royal Society. After a period Raspe's name was struck off the rolls of the Society and he took to writing for a living, and while acting as storekeeper and assayer at Dolcoath Mine in Cornwall wrote the original part of "Baron Munchausen's Narrative". Later on, Raspe obtained money from the public-spirited Scottish baronet, Sir John Sinclair (1754–1835), by pretending to discover gold and silver on his estate at Ulbster, Caithness, an incident commemorated by Scott's character "Dousterswivel". Sinclair, it may be added, was one of the subscribers to Raspe's translation of Born's "Amalgamation".

Research on Coal Utilization

SIR EVAN WILLIAMS announced, in his presidential address to the British Coal Utilization Research Association on December 17, that a scheme utilizing £1,000,000 in five years for research on coal has been prepared. He said that this is by far the largest co-operative research scheme ever undertaken in Great Britain for the development of an industrial asset. The scheme has been approved by the Department of Scientific and Industrial Research, which has undertaken to contribute £50,000 a year to the cost, and £250,000 over the five years. The Mining Association will contribute £80,000 a year and £400,000 altogether, and the balance of £70,000 a year will be provided by associations of manufacturers who make plant and equipment for using coal.

Among the purposes of the scheme is the development of new processes based on coal which will create employment and strengthen export trade. Improvements in methods of using coal for light and power, for the production of materials for the chemical industry, the development of such substances as plastics, and the production of liquid fuels will be among the subjects of investigation. Sir Evan Williams said that the Ministry of Planning has asked the Coal Utilization Research Association to carry forward to the production stage economical domestic heating appliances which have been devised so that they may be procurable for the post-war house building programme.

Geographical and Geological Research in the U.S.S.R.

ONE of the first aims of the Russian Academy of Science founded by Peter I in 1724 was the geographical study of the country's natural resources and populations. Geography and geology have also been kept in the forefront of the manifold activities of the present Academy of Sciences. In 1920 a systematic scientific study of raw materials was undertaken with the view of co-ordinating the industrialization of the Soviet Union with the distribution of essential minerals. The work has borne fruit, for example, in the development of great apatite, copper and nickel industries in the arctic tundras, and of the sulphur industry in the sands of Karakum, and in the exploration of the vast oilfields known as the 'second Baku', lying between the River Kama and the Ural Mountains. These last explorations proved of inestimable value when the wholesale transfer of industry to the east was made necessary by the German invasion.

During the past twenty-five years the Academy has sent more than five hundred expeditions to every part of the Soviet Union to study geological and agricultural resources. In 1917 only 10 per cent of the country had been surveyed geologically; now the proportion is 50 per cent. Maps of soils and vegetation have also been prepared, as well as general maps for European Russia. Geological calculations show that the Union occupies first place among all countries of the world in respect of resources of iron, manganese, apatite, phosphorites, potash salts and niobium, and second place in respect of coal, zinc, lead and nickel.

The Ukrainian Academy of Sciences

AN account of the war-time activities of the Ukrainian Academy of Sciences has recently been received from the U.S.S.R. Early in the War the Academy was transferred to the interior of the country, where it resumed work. It was faced with complex problems which had to be tackled at short notice, in particular the readjustment of its entire scientific activities to meet the requirements of national defence and an expanding production programme. At the present time a large part of the Academy's work relates to aircraft and tank construction. Comprehensive studies are being made of the power resources of the Urals and Bashkiria, where new war industries have sprung up.

Biological institutes are investigating new methods of treating wounds and preventing infection. An anti-reticular cytotoxic serum has already been placed at the disposal of hospitals and has proved its value in accelerating healing processes. Close contact has been established between the Academy research workers and the war factories. A special technical committee has been set up to co-ordinate the Academy's research programme with the demands of the war effort. Another committee is studying the scientific problems of reconstruction that will require immediate solution when the Ukraine is liberated from the German yoke.

The Sky in North Africa

A SECOND edition of the "Star Atlas for the Latitude of Egypt", compiled by H. E. Hurst, M. R. Madwar and A. H. Samaha, and published by R. Schindler, Cairo, will be welcomed by members of the British forces campaigning in North Africa. It is designed for use in latitude 30° N., but can be employed without difficulty between 20° and 40° N.; it may therefore be of service in North India, South China, and the southern United States as well. It consists of six circular star charts covering the whole sky visible throughout the year in those latitudes, the centre of each chart being the zenith of the observer and the circumference his horizon. The successive charts represent the appearance of the sky throughout the twenty-four hours of a given day at four-hour intervals, or alternatively throughout the year at a given time of night at two-month intervals. A transparent graticule of the same size of the charts can be used to estimate altitudes and azimuths of the stars.

The text accompanying the charts illustrates their use and gives a clear description of the apparent movements of the stars, the planets, and the sun and moon, and even touches upon the modern conception of the structure of the galaxy. In solving many practical problems the atlas may prove invaluable; for example, in choosing a suitable guide star for marching on a given bearing, in reckoning the azimuth of a terrestrial object, and in estimating the time during the night. Such information must often have been in demand in the quick-moving campaigns of the past two years. When the charts are not employed in such immediately useful ways, the accompanying notes may awaken the scientific interest of those living in lonely camps with little to occupy their spare time. The atlas is handy in size and the charts are excellently drawn and reproduced.

Production of Synthetic Rubber in Sweden

THE scarcity of rubber is being felt more and more in Sweden. While through a rapid perfection and large-scale adoption of producer-gas the motor fuel problem has been relatively satisfactorily solved, it is now the shortage of rubber and lubricants that is the great cause for anxiety and which has made necessary the imposition of further restrictions on motor traffic. To try to improve the situation, experiments with the production of synthetic rubber have been going on for some time at various institutions. Promising results have been reported from the Physico-Chemical Institute at Uppsala, where experimental production has been carried on under the guidance of Prof. The Svedberg, as well as by the Swedish cellulose concern, Mo and Domsjö, which has evolved a product that is stated to be able to replace rubber for many purposes and which will be produced on a commercial scale in the near future. A young Swedish scientific worker, Dr. Gösta Ehrensvärd, of the Wenner-Gren Institute in Stockholm, has succeeded in developing a kind of artificial rubber which seems to possess several good qualities. Production on a small scale has been going on for some time at one of the rubber factories of the Swedish Co-operative Wholesale Society, which is supporting his researches and will probably exploit the new product. It belongs to the so-called 'thioplast' products, the weak point of which has hitherto been that they could not be vulcanized at a high temperature. This can, however, be done with the Ehrensvärd rubber. The unpleasant odour that formerly characterized such products has also been eliminated. Nothing has so far been said about the composition of the new product or of what raw materials it is being made, except that it is based on domestic raw materials and that the Swedish forests, in this as in so many other cases, will play an important part.

Photographic Analysis of Motion

A LECTURE on the "Photographic Analysis of Motion" was delivered at the Royal Institution on December 11 by Mr. E. R. Davies, director of research, Messrs. Kodak, Ltd. He said that the value of photography in the analysis of movements too rapid for the eye to follow was demonstrated, and the method successfully applied, in the classical investigations of Muybridge and Marey before the introduction of the dry plate in 1871. The great convenience of the new process compared with the laborious wet-plate technique, and its enhanced sensitivity, brought about many triumphs towards the end of the nineteenth century. The movements of animals and the flight of birds were analysed; projectiles travelling at speeds in excess of that of sound photographed; and the propagation of flames in gaseous combustion was followed. Modern progress had depended to a large extent upon the introduction of the cold cathode discharge tube in place of the far less luminous electric spark; on advances in the design of cinematographic and other types of camera; on the introduction of photographic materials of greatly increased sensitivity; and on the application of the photo-electric cell and the microphone to the problem of synchronizing the action with the camera exposure. Instantaneous photographs can now be taken with exposures of less than a millionth of a second and cinematograph pictures with a frequency in excess of 4,000 a second. A valuable tool has become available to science and industry, and has proved its worth in many fields. Its use in the design and testing of high-speed machinery is of particular importance at the present time.

Cancer-producing Mineral Oils

ADDRESSING a recent meeting of the Manchester University Branch of the Association of Scientific Workers, Mr. R. Lyth described how methods of preventing certain types of occupational cancer have been discovered. External cancers which are prevalent among Scottish shale oil workers have also increased among cotton spinners, since the introduction of mineral lubricating oils. In the Cancer Research Department of the University of Manchester, cancers have been produced in mice by repeatedly painting their skins with mineral oils. Shale oil was found to be much the most active carcinogenically, while Russian oil was one of the least active oils. The refractivity $(\mu - 1)/D$, where μ is the refractive index and D the density, could be roughly correlated with the carcinogenic properties, and used as an index of them. In the laboratory, various methods of reducing the activity of oils were found, but the cotton industry has found it more practicable to avoid the use of the more dangerous oils such as shale oil. For the shale oil workers themselves, the regular use of certain ointments has proved beneficial. Efforts to isolate the carcinogenic constituents of mineral oils have not yet fully succeeded. The meeting learnt with regret that the Cancer Research Department of the University of Manchester is being closed.

Frequency Stability of Radio Circuits

AT a meeting of the Students Section of the Institution of Electrical Engineers held on November 16, Mr. C. W. Eggleton read a paper on "The Frequency Stability of Tuned Circuits". The author dealt with the conditions with which it is necessary to comply in the design of commercial radio receivers in order to secure a satisfactory degree of frequency stability in the various tuned circuits of the receiver. The majority of broadcasting receivers in use at the present time are of the supersonic heterodyne type using a local oscillator, and it is the frequency stability of this oscillator which usually determines the stability of the whole receiver, particularly when the required reception is within the short-wave band. Variations of the frequency of any tuned circuit are occasioned chiefly by the effect of temperature, and to a lesser extent by condensed moisture, on the electrical characteristics of inductance coils and condensers. In the paper, the author directed attention to the desirable properties of the materials used in the construction of these components, and to the importance of various features of design. An important point in connexion with the layout of the whole receiver is to ensure that the local oscillator and the main radio frequency circuits are kept as far away as possible from the power frequency components, which largely form the main source of heat generated in the receiver.

London Gulls

IT is reputed (*Countryside*, 12, No. 5, 93; 1942) that it is exactly fifty years since flocks of gulls began to winter on the London Thames, in the severe winter of 1892. Most of these birds are black-headed gulls, but whether or not the severe winter of 1892 was the origin of gulls frequenting the Thames embankment in numbers is not accepted by all ornithologists. T. L. Bartlett notes that sixty years ago the occasional appearance of gulls in London caused unusual interest amongst ornithologists, and although there were occasional records of gulls passing up-river in severe weather, the first winter occupation of central London by black-headed gulls appears to be the severe winter of 1892 at Blackfriars Bridge, where new legislation protected them from gunshot. But the black-headed gull has not really changed its habit: it was always known as an inland as well as coastal bird. The difference in the past fifty years has been its great increase in numbers—which may be from biological reasons—and its protection under the bird laws which give it encouragement to stay on waters where formerly it was persecuted and driven away. Bartlett, however, suggests also that they were encouraged to winter on the Thames after 1892 by the public feeding the gulls with large sprats, and fifty years of embankment feeding with bread have changed its ways to a town gull. The habits of Thames gulls have, however, been given exaggerated importance. Similar changes in the status of the black-headed gull have occurred in the Mersey and other rivers where there was no great public feeding of the gulls, and the flocks became regular winter inhabitants of the park lakes.

Regional Survey Atlas of the Croydon District

THE ambitious project for a regional survey atlas covering some 200 square miles around the Borough of Croydon was begun by the Croydon Natural History and Scientific Society so long ago as 1913. Despite the difficulties of war-time conditions, it has been continued by the issue this year of a third series of maps and printed matter (*Proc. Croydon and Dist. Nat. Hist. and Sci. Soc.*). In contrast to similar local surveys which have been attempted in other parts of Great Britain, the Croydon scheme is based essentially on the idea that a regional survey is never of necessity complete, and hence the actual work is to be contained in a loose-leaf binder which was issued with the first series of maps; the contents as originally planned can therefore be added to as experience and the progress of knowledge may dictate.

The two previous issues of maps have included base maps, maps dealing with rainfall, relief, drainage and a number of historical maps as well as some referring to population and planning. The present, or third, issue contains only one map—of bronze age remains—but has the textual statement by Mr. Fagg on geological structure and history, illustrated by geological sections, and an account of the natural vegetation, together with a list of plants normally found on the chalk of the region, a section contributed by Mr. C. T. Prime. The description of the bronze age map is by Mr. A. W. G. Lowther. It is to be hoped that there will be sufficient public support for the venture to enable it to be continued and to afford the necessary encouragement to Mr. C. C. Fagg, who has been the organizer.

Indian Forest College, Dehra Dun

THE Progress Report of the Indian Forest College, Dehra Dun, 1940–41 (Manager, Government of India Press, New Delhi, 1941), states that the College was opened in May 1938, after a period of closure, for the training of candidates for the Superior Forest Services of the various Provinces and States of India. The course extends over two years, each class completing its course before a fresh class is admitted, so that there are no overlapping classes. This first course lasted from May 1938 until March 1940. The report in question covers the first year's work of the second course, which was to end in March 1942. At the prize-giving at the end of the first two-year course the President and Principal of the College both spoke in laudatory terms of the work achieved and the type of man and training which the College is turning out.

The movement will be watched anxiously by old Indian forest officers, who have seen the growth of, and the fine results attained by, the Indian Forest Service. They ask how will the standard be maintained by a series of devolutionized, entirely independent forest departments in the provinces, staffed in the higher grades in the future by men trained in a college the staff of which has had no opportunities of rubbing shoulders with confrères in their own subjects. Moreover, men trained in this fashion will not have had the advantage of training in one of the old universities, where they mix with men who are getting other courses of education; and finally they will not have the opportunity of combining this training with visits to European continental forests which is so desirable.

The Night Sky in January

NEW moon occurs on January 6d. 12h. 37m. and full moon on January 21d. 10h. 48m. The following conjunctions take place during the month: Jan. 4d. 10h., Mars in conjunction with the moon, Mars 5° S.; Jan. 7d. 22h., Mercury in conjunction with the moon, Mercury 3° S.; Jan. 16d. 10h., Mercury in conjunction with Venus, Mercury 2·7° N.; Jan. 16d. 19h., Saturn in conjunction with the moon, Saturn 3° N.; Jan. 20d. 12h., Jupiter in conjunction with the moon, Jupiter 3° N. Occultations of stars brighter than magnitude 6 are as follows, the times referring to Greenwich:

	d.	h.	m.			
Jan.	14	19	43·2	μ	Ceti	D
	15	17	37·7	f	Tauri	D
	16	17	31·0	γ	Tauri	D
	16	23	25·6	θ′	Tauri	D
	16	23	46·6	75	Tauri	D
	17	00	32·9	264B.	Tauri	D
	25	00	29·3	χ	Leonis	R

Mercury attains its greatest elongation, 19° E., on Jan. 8. Venus sets about an hour after the sun in the middle of the month and is not very favourably placed for observation in Great Britain. Jupiter and Saturn continue to be well placed for observation, the former southing about midnight and the latter at 20h. 40m. in the middle of the month. The earth makes its closest approach to the sun on January 2.

Announcements

SIR JOHN C. G. LEDINGHAM is to retire on March 31 from the post of director of the Lister Institute of Preventive Medicine, which he has held since 1930. To succeed Sir John Ledingham in the directorship, the Governing Body of the Institute has appointed Dr. A. N. Drury, Huddersfield lecturer in special pathology, University of Cambridge, and member of the scientific staff of the Medical Research Council.

AT the annual general meeting of the British Mycological Society on December 12, Dr. S. P. Wiltshire, director of the Imperial Mycological Institute, Kew, Surrey, was elected president for 1943.

THE Board of Trinity College, Dublin, has invited Prof. J. M. O'Connor, professor of physiology in University College, Dublin, to deliver the John Mallet Purser Lecture in 1943.

THE Central Council for Health Education is making plans for its 1943 Summer School. The School will probably be held at the Chelsea Polytechnic during August 4–14, and will deal with the teaching of biology and with health education generally. While teachers of biology will find the full ten days of value, educational administrators and youth leaders will find the first three days of the School of special interest to them. Further details may be obtained from the Education Officer, Central Council for Health Education, Tavistock House, Tavistock Square, W.C.1.

Experimental Evidence of the Existence of Element 85 in the Thorium Family

BESIDES the branching of the C products in the three radioactive families, Mlle. Perey and Lecoin[1,2] have shown another branching in actinium, leading to the creation of element 87. Turner[3], considering the regularities in the distribution of isotopes, has concluded that actinium A, thorium A and radium A should also be β-active. Thus, the element 85 would be created. We have therefore tried to separate element 85 from some 40 mgm. of radiothorium which we had at our disposal.

As 85 is a halogen, it should sublime easily like its homologue iodine, so it seemed simplest to separate it by sublimation in the following way. In order to obtain the disintegration products of thorium A, particularly 85, in sufficient quantities in a short time, the thorium emanation ($T = 54$ sec.) was blown for about 20 min. between two copper sheets 2 cm. × 1 cm., one negatively and the other positively charged, thus obtaining the radioactive deposit on the negative electrode, from which the 85 was sublimed at the temperature of a hot oil bath (about 180° C.) on to a constantly cooled silver wire. After 10 min. of sublimation this wire was removed and placed in a Wilson expansion chamber. (The arrangement for the accumulation of the radioactive deposit was such as to eliminate any possibility of contamination with radiothorium or thorium X. The Wilson expansion chamber was in a different wing of the Institute, and thus any other accidental contamination was also excluded.)

The following observations were made:

For the first 10–20 min., varying in different extractions, no tracks were observed in the expansion chamber. Then α- and β-tracks began to appear, very slowly, from different parts of the gas, or from the walls of the expansion chamber, but practically never starting from the silver wire. The α-tracks were always observed in pairs. During the expansions a halo of mist surrounded the silver wire for the first 30–40 min. from the time it was placed in the expansion chamber, and afterwards disappeared. The pairs of α-tracks continued to be present in the expansion chamber for about two days.

Both tracks of the pairs seemed to start from the same point. Stereoscopic photographs, however, showed that their starting points were not identical, but were separated by a maximum distance of 5 mm.

Whenever the disintegration took place at the best illuminated level of the expansion chamber, the pair of α-tracks was seen to be accompanied by a β-ray with the same starting point as one of the α-tracks. This β-ray was so often observed that it is more probably a primary ray than a secondary ray produced by an internal conversion of a γ-ray.

Many photographs were made of the double tracks; and on some the β-track also seemed faintly visible, the lighting system being too weak and the light power of the objectives of the photographic camera being only 1 : 4 : 5. Without an automatic chamber connected with a photographic camera, there was almost no chance of photographing the tracks in the gas in the middle of the expansion chamber so that the whole length of both α-tracks could be measured; and as, owing to the War, films were difficult to obtain, they could not be wasted in the faint hope of obtaining such a disintegration. Nevertheless, the double and even the triple tracks were observed so frequently that their existence could be taken as established.

From the above observations one could conclude that we had succeeded in separating and in placing in the expansion chamber a hitherto unknown element and its disintegration products. The method used for separating this element suggests that it is 85.

Although the disintegration thoron $\xrightarrow{\alpha}$ thorium A $\xrightarrow{\alpha}$ thorium B would produce pairs of α-tracks with the same starting points, the observed tracks could not be due to this contamination for the following reasons:

(1) If the expansion chamber had been contaminated with the thorium emanation, as its period is only 54 sec., the initial amounts would have to have been enormous to continue to produce pairs of α-tracks after two days, as were found in our experiments.

(2) A contamination with thorium X, of which the disintegration products would again be thoron → thorium A → thorium B, is disproved by the fact that practically no tracks were observed starting from the silver wire, by which alone thorium X could have been brought into the expansion chamber, and from which its α-tracks would have been observed to start.

(3) From all the photographs taken, only one α-track of the pairs (the one connected with the β-ray) could be measured exactly from its beginning to its end, its length being 5·2 cm. (15° C., 760 mm.). In another photograph the incomplete length of one of the tracks of the pair was about 7 cm. These lengths also show that the pairs in our experiments are not due to the thoron → thorium A → thorium B disintegration, since the lengths of these α-tracks are much shorter.

A possible explanation for the tracks appearing in the gas and from different parts of the expansion chamber, instead of from the source (the silver wire), could be given by the suggestion that 85 filtered away from the source in a very short time after being

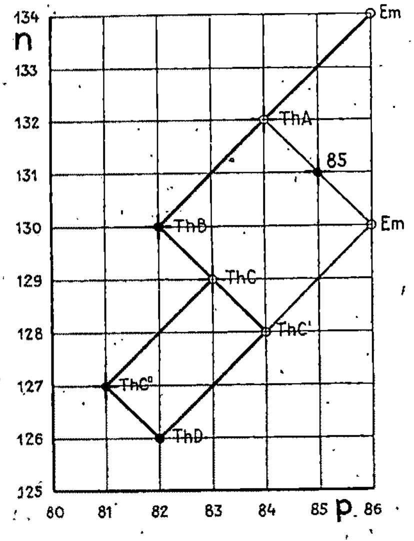

Fig. 1.

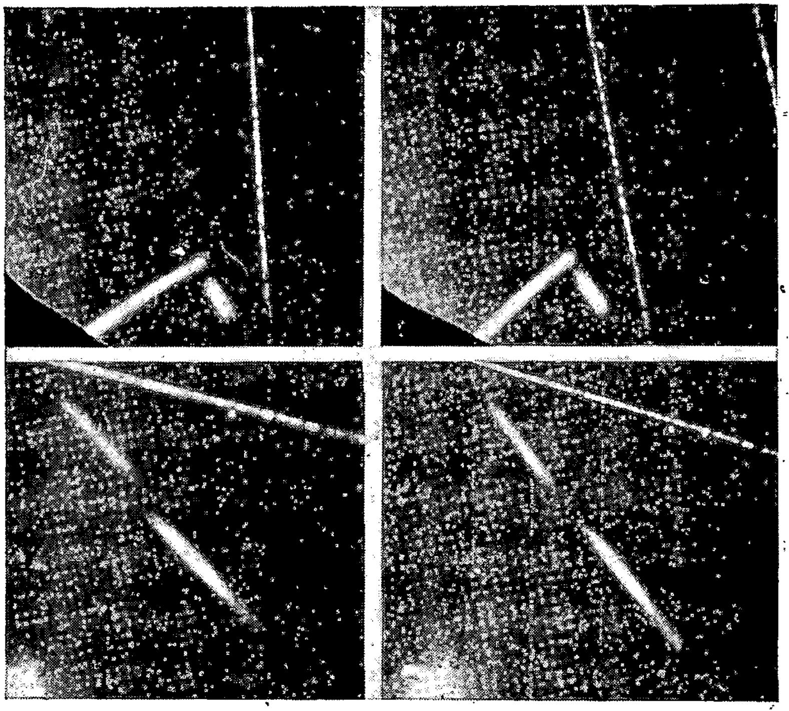

Fig. 2.

placed in the expansion chamber, due to (1) its high vapour pressure and (2) its predicted faculty of easily creating highly volatile compounds. The silver wire was cooled during the sublimation and until it was placed in the expansion chamber. During that time a coat of moisture deposited itself on it. The halo of mist which was observed during the first 30–40 min. may have caused the apparent retardation of the tracks, as, so long as it was present, the tracks starting from the silver wire may not have been visible and the 85 could have filtered away during that time.

The accompanying diagram (Fig. 1) attempts to give an explanation of the disintegrations observed in our experiments.

After the normal disintegration of the thorium emanation by α-radiations into thorium A, the branching takes place. The main part of thorium A disintegrates by α-radiations into thorium B and its after-products. An extremely small portion would disintegrate by β-radiations into the element 85, which would continue to disintegrate by further β-radiations (probably with a fairly long period) into a new isotope of the thorium emanation $^{216}_{86}\mathrm{Th}\,n$, for which the neutron proton relation $n/p = 1{\cdot}512$, therefore suggesting a much bigger probability for an α-disintegration, which manifests itself by a much shorter period than that of the known thorium emanation, for which $n/p = 1{\cdot}558$. The emanation $^{216}_{86}\mathrm{Th}\,n$ would, then, through an α-disintegration, produce an isomeric thorium C′ atom, which would disintegrate by an α-transition into inactive thorium D.

Thus, the triplets which were observed to start in the gas could be accounted for as follows: the β-ray belonging to the atom 85; one of the α-rays belonging to the atom of the new isotope of the emanation $^{216}_{86}\mathrm{Th}\,n$; the other α-ray belonging to an isomeric thorium C′ atom.

The two stereoscopic photographs (Fig. 2) of the pairs of the α-tracks starting in the gas which are reproduced herewith show the difficulty of measuring their length.

As a tribute to the scientific work of our two countries, we propose to name the element 85 'anglo-helvetium'.

Our thanks are due to Prof. Adolf Liechti, director of the Röntgen Institute in the University of Berne, who facilitated and encouraged the above work, which was carried out in his institute; to Prof. P. Scherrer, of the Eidgenössische Technische Hochschule of Zürich for the loan of the Wilson expansion chamber; and to Mr. Albert Benteli of Berne for his trouble in supplying and preparing the radio-thorium, which was provided by Dr. A. Wander of Berne for cancer research in the Röntgen Institute in the University of Berne.

Influence of Potassium on Sugar Metabolism

In a recent communication[1] Leibowitz and Kupermintz have demonstrated that in cultures of *E. coli* in *M*/60 glucose containing potassium chloride in a concentration of *M*/250 the potassium stimulates the utilization of the sugar in a similar manner to that noted by Pulver and Verzar[2], in the case of yeast. Immediately before the commencement of fermentation the potassium enters the yeast cell, reappearing in the external medium during fermentation proper. This initial entry may be connected with intracellular glycogen formation. The Donnan equilibrium would suggest that during rapid carbohydrate oxidation potassium should leave the cell, and enter when carbohydrate is being elaborated[3]. The possibility that the cell membrane may exert some effect on carbohydrate metabolism is suggested by observations on blood stored for transfusion purposes[4].

In order to investigate the influence of the cell membrane, we compared the stimulation by potassium (in concentration of about 0·005 per cent KCl) of the degradation of glucose in dilute solution (0·5–0·6 per cent) by yeast cells and by cell-free yeast extract. The effects of uranium instead of potassium and together with potassium were also examined in the cases of cells and cell-free extract, owing to the report by Zwaademaker[5] and others that in some physiological processes equi-radioactive quantities of potassium and uranium are interchangeable but antagonistic when employed together.

It was found that (i) potassium stimulates glucose

o a similar extent when cells and cell-
ıre used; (ii) that in both cases phos-
ates the glucose metabolism to about
gree as potassium, which is interesting
f the statement by Rapoport and Guest[6]
the minimum lethal doses of potassium
te ions are of the same order; (iii) that
ion is most marked when fermentation
ed only to a slight extent; (iv) that
er's relationship for potassium and
s not appear to hold for the degradation
y yeast or yeast extract.

otato Disinfection by Conveyor Belt Dipper

recently one of the factors limiting large-
lication of disinfection of potato seed for
ention of various diseases was that no suit-
liance had been evolved for handling large
seed potatoes. During 1940 and 1941 con-
tonnages of early varieties were dipped in
on lifting by a simple derrick erected over
ank of the solution. Although effective, this
entailed considerable labour and left much
esired.

der to provide for the disinfection of large
ies of seed potatoes expeditiously and with
m labour and damage, a plant has now been
, at our suggestion, utilizing the conveyor belt
e. The essential feature is a dipping tank
approximately 600 gallons, provided with a
or belt operating below the surface of the
n. This dipping plant can be worked in con-
n with the usual type of grader, the potatoes
lelivered from the picking belt of the grader
wooden chute into the solution, where they
horizontally for approximately one minute
e then elevated out of the tank at an angle of
he elevator delivers them directly into boxes
are immediately removed to the open field
acked there for drying, which takes only a few
es.

ing the present lifting season, more than 1,000
f Ninetyfold and Arran Pilot seed potatoes have
reated by a pair of these plants, installed by
Tractors, Ltd., Coupar Angus, for Mr. T. A.
erspoon of Eassie. The disinfectant used was
f the well-known organo mercury potato dis-
ants.

a result of the large-scale experience gained this
it is expected that the value of this principle
proved potato dipping will become established.

Civil Defence Against War Gases

THE article on "Civil Defence Against War Gases"[1] is substantially correct, but contains one serious and one minor error. It states that after the War of 1914–18 "the nations solemnly renounced the use of gas at a Geneva conference, a pledge which has so far been kept—nor is there any reason why it should be broken". The Italians quite certainly used gas against the Abyssinians. There is evidence[2] that the Germans have killed many thousand Jewish civilians with poison gas.

There is thus no moral objection to using poison gas against Italy, and, if the above reports are confirmed, none to using it against Germany. For poison gases are no more inhuman than other weapons used by both sides. I should prefer dying from lung œdema due to phosgene than from a septic wound or severe burns. There may be tactical objections at present, but if at a later stage in the War these cease to hold, I trust that the United Nations will not hesitate to use poison gas if experts think this will save the life of a single Allied soldier, sailor, or airman.

The other doubtful statement is that "everyone in Great Britain has a gas mask and knows how to use and care for it". They ought to know, but very many do not. The present lull in raiding might well be used to see that more of them do.

Finally, the opinion expressed as to the limited effects of a gas attack, though valid against the wild statements which were commonly made before the War, may require some modification in view of the new technique of concentrated raids. If gas bombs were dropped as widely dispersed in space and time as high-explosive bombs were in the London raids of autumn 1940, they could nowhere produce a lethal concentration of non-persistent gas except in the immediate neighbourhood of individual bombs. But if some hundreds of tons were dropped within an hour in a restricted area, they might generate a gas cloud of a dangerous density.

For this reason I think that the danger of a gas attack on some large British city is rather greater than readers of the article might believe, and the need for preparation more urgent.

A Varnish for Fixing Smoked Tracings

IN damp weather it has been noticed that a good many varnishes produce a white precipitate when used for fixing smoked tracings after experimental physiology work. This naturally interferes with the final tracing and sometimes forms all over it, thereby obliterating the original work. We have prepared a great number of varnishes, and of them the following has been satisfactory. A white haze does form even with this varnish in a moist atmosphere, but it disappears on drying. The following is the formula for the varnish: gum juniper, 60 gm.; colophony resin, 13 gm.; castor oil, 5 mil.; industrial methylated spirits, 200 mil. This produces a glossy finish, ideal for demonstration purposes and even class work.

ELECTRIC STRENGTH OF VARNISH FILMS

IN a paper entitled "Intrinsic Electric Strength and Conductivity of Varnish Films and their Variation with Temperature" (*J. Inst. Elec. Eng.*, 89, Pt. 1, No. 23; November 1942), A. Morris Thomas and Miss M. V. Griffith discuss recent advances in the theory of the intrinsic electric strength of solids, and describe methods for the preparation and testing of samples of baking insulating varnishes and shellac-varnish films for the determination of their intrinsic electric strength. The varnishes tested were a clear baking oil insulating varnish, a black baking bituminous insulating varnish, a synthetic-resin insulating bakelite varnish, and a pure de-waxed lemon shellac varnish.

The results of the tests made on a thickness range of 0·02–0·1 mm., and a temperature range down to −196° C., are reported. The investigation also includes conductivity measurements, effect of different ambient conditions (immersion media and applied pressure), time/voltage tests, and the effect of centrifuging and filtering and comparison tests on varnish-impregnated paper films, which were made to establish the validity of the method of test and to assist interpretation of the results.

The large and continuous increase of intrinsic electric strength with decrease of temperature down to −196° C. which is found disposes of the assumption hitherto made by some investigators that this quantity is independent of temperature. Consideration of the results in relation to the recent theory proposed by Frohlich to account for a temperature-dependence of the character obtained indicates that this theory in its present form is not applicable, but an alternative explanation is suggested.

As the results of the research, the investigators reach the following conclusions. The intrinsic electric strength of varnish films is probably independent of thickness from 0·02 mm. to about 0·1 mm. at all temperatures, except that clear varnish films show a small decrease with the thicker samples at 90° C., and at low temperatures 0·04 mm. was the maximum thickness tested. The values for all four types of varnish investigated at −196° C. lie between 8,000 and 9,000 kv./cm. and decrease approximately linearly with increase of temperature up to 0° C., the exception being clear varnish. Above about 0° C. the decrease continues at a slower rate up to 60° C., and the values then tend to increase slightly up to 90° C., except that shellac gives a sharp fall. As the rates of decrease with increase of temperature differ, the values diverge, so that at 60° C. the maximum values are approximately 4,900, 3,300, 2,600 and 2,200 kv./cm. for the bakelite, shellac, black and clear varnish films respectively. The intrinsic electric strength of the bakelite varnish films is independent of time of application of voltage within the experimental range, but the other varnishes show decreases in maintained-voltage tests, which, however, may be a consequence of local defects due to inclusions or lack of film uniformity.

Relatively large inclusions of a dielectric such as cellulose in the form of paper are found not to affect appreciably the intrinsic electric strength of varnish films. The variation of the conductivity of varnish films with temperature is apparently of a complex nature and is not of a type which enables definite conclusions to be drawn with regard to the mechanism,
although the results are qualitatively
if it be supposed that ionic conduction
and electronic conduction at low, tem
results may be considered in relation
of the breakdown of organic solids rece
by Frohlich. If electronic conduction on
then the intrinsic electric strength of a
consisting of long-chain crystals should
increase of temperature, but the introdu
groups into the molecules may outwei
and cause a decrease. For this type o
occur, it is necessary that the tempera
ciently high to enable certain of the mol
to rotate, and such an effect may be r
an increase of dielectric constant.

The investigations of phenolformalde
films by Hartshorn, Megson and Rushto
an increase of dielectric constant due to
tion in substances of this type does not o
temperature of 20° C. is attained; th
constant then rises from about 3 to a val
80° C. This region corresponds to that
the intrinsic electric strength of the va
remains approximately constant, so that
in its present form is inadequate to e
results. There remains a possibility that
of the course of the temperature variat
occurs roughly at normal temperature
related to the change in the conduction
at about the same temperature. Referenc
to the agreement of the results with those
on amorphous glass. It is suggested t
materials of the type which have a colloidal
a falling intrinsic electric strength/te
characteristic may be explained by the rel
of electronic or ionic movement along
surfaces.

Association.

INTUITIVE KNOWLEDGE

IN a paper on intuitive knowledge in the
Mind of October, 1942, Prof. R. I. Aaron
the present position of the time-honoured
that there are certain propositions which th
mind can know without any shadow of
possibility of error. This doctrine, a legacy i
pean thought of the philosopher-scientist D
who took the deductive reasoning in geometr
pattern of scientific thinking and the self-
axioms of Euclidean geometry as the four
thereof, has come to seem less compelling n
those axioms are no longer regarded as self
by any educated person.

The author agrees, however, that to concl
this that the whole notion of intuitive k
must be discarded would be precipitate. T
do so, assert that any so-called piece of in
knowledge is either merely a statement a
certain linguistic forms are used (for exa
I know that 'no fishes have hair' necessit
'no creatures with hair are fishes', I am
knowing anything except the rule by w
English sentence can be transformed into a
or, if such knowledge goes beyond words to
world, it can never be absolutely certain (for
ample, when I know that my hand is before

m ing my pen across the page, there is some possi- fre , however small, of error). This latter con- ph n is based on the assumption that, as all state- th about the empirical are based on evidence, in e may at any given point be more evidence t ncoming which would shake the certainty of the a ment.

defence of intuitive knowledge the author main- ins that there are propositions which depend on dence but yet are absolutely certain because there uch a thing as conclusive evidence. For example, o know my hand is now moving my pen across page. This is an example of undoubted know- R e. This has been said before, of course, but it m worth while saying again in face of modern det ncies to dissolve away knowledge into mere ng about a universe hidden behind the veil of tion.

PERICARDIUM AND ERICARDIAL GLAND IN THE LAMELLIBRANCHIA

most recent number of the *Proceedings of Malacological Society of London* (25, Pt. 2) ly occupied by an important paper by Dr. n M. White on "The Pericardial Cavity and ial Gland of the Lamellibranchia". Present re workers on the morphology of the Lamel- s will be grateful for this paper which, without sary verbosity, summarizes existing know- n the subject and adds materially to it. A nge of material was examined, some eighty from seventy-one genera and forty-six . Excellent figures are given of conditions in species.

pericardial gland arises as paired groups of the anterior part of the pericardium. It may over the auricles only or over the dorsal and surfaces of the pericardium and into neigh- g parts of the mantle. In both cases it is and both pairs of glands may be present. unction is certainly excretory but the exact n of this to that of the kidneys remains some- bscure. In only one family (Donacidæ) and lated genera was the gland absent. The case a is interesting. Here the gland was found three out of seven species. Miss White es this with the presence of a pre-oral gland, ng Stenta who described this strange organ. sent in those species in which the pericardial is best developed. There is matter for further gation here. The pre-oral gland opens into ra-branchial chamber and is therefore unlikely oncerned with the extrusion of fluid excrement, would have to pass through the gills. On the hand, it could produce solid excrement because ould be ejected with other waste particles by the *inhalant* opening.

ariable relations between the heart and the m are mentioned. Typically, the rectum tra- e heart, but in a few species it passes above the heart. Miss White discusses possible al relations between the two organs, but em improbable and it is more likely that the t relations arise from purely morphological The interesting discovery was made that the may extend into the mantle in species of Arca, pondylus and Chama, a condition hitherto recorded ly in the Mytilidæ and Anomiidæ.

INSULATOR GLAZES

AN article by E. Rosenthal in the *Electrical Review* of November 27 discusses the influence of insulator glazes on porcelain, having particular reference to high-voltage insulators. Under a strong microscope the surfaces of unglazed ceramic materials show minute projecting peaks which make it evident that the quality of the surface has a great bearing on the surface resistivity. This, in turn, is largely dependent on the humidity skin which, in a moist atmosphere, forms on any surface to a thickness that increases with the surface roughness and with atmospheric humidity. With 30 per cent humidity, the surface resistance of unglazed porcelain ranges between 20 and 40 $\times 10^{12}$ ohms / sq. cm., but with 98 per cent humidity it is only about $0{\cdot}001 \times 10^{12}$. This decrease in surface resistivity is smaller the smoother the surface. In a dry atmosphere glazed porcelain has approximately the same surface resistance as unglazed porcelain, but in a humid atmosphere of, for example, 98 per cent humidity the figure becomes $0{\cdot}1 \times 10^{12}$ ohms/sq. cm. This dependence of surface resistivity on the quality of the surface and on the humidity content of the atmosphere is a characteristic not only of porcelain but also of all insulating materials.

The glaze on a porcelain insulator is composed of raw materials similar to those used for the body, but fluxes are added which cause the mixture to melt at the firing temperature of the insulator (1,300–1,400° C.). High-temperature insulator glazes (fired at a temperature of 1,300° C. and higher) have not only a very great influence on the surface resistivity of the insulator but also on its mechanical and physical characteristics. One of the most important factors which influence the mechanical characteristics of the glazed body is the ratio of the heat expansion of the glaze to that of the body. The most suitable glaze must be found by numerous experiments (by trial and error) for each and every body. The tensile strength, the modulus of rupture and other mechanical characteristics may be improved very considerably by the application of a glaze, the thermal coefficient of which bears the proper ratio to the thermal coefficient of the body.

The resistance to sudden temperature changes, however, may be more favourably influenced by another glaze. If the thermal expansion of the glaze does not agree with that of the body, a considerable decrease in mechanical strength may result.

Many experiments on tensile strength have been carried out in different countries and the results have been published by various authorities. In the United States it is reported that in special cases the tensile strength is increased by as much as 80 per cent by a suitable glaze, and an increase of 40 per cent is quite normal. Similar results have been obtained by Continental research workers, the tensile strength of unglazed porcelain being given as 240–320 kgm./sq. cm. and of glazed porcelain as 300–500 kgm./sq. cm. Tests carried out in English factory laboratories give similar results. The application of a suitable glaze not only increases the tensile strength but also the other mechanical characteristics. For example, the minimum compressive strengths of unglazed cylindrical test specimens possessing cross-sections of 160, 80 and 20 sq. cm. are 900, 1,000 and 1,700 kgm./sq. cm. respectively. Corresponding figures for glazed cylinders are 2,000, 2,300 and 4,300 kgm./sq. cm. These considerations apply only to porcelain glazes which fuse at the vitrification temperature of the porcelain as generally used in high-voltage insulator manufacture.

Glazes which are applied to the finished ceramic article and which are fused in a second firing at a lower temperature behave differently and are not able to increase the mechanical stress of the ceramic article. In contradistinction to high-voltage insulator glazes, this type of glaze must contain strong fluxes like lead oxide, etc., which are not present in the porcelain body. These glazes form, with the surface layer of the porcelain, combinations which may behave very differently from the body. The composition of the glaze does not in this case play so predominating a part as in the case of high-tension insulator glazes.

In insulator design, much use is made of the strengthening effect of the glaze on insulator bodies. Previously, the attachment of the porcelain to the metal work was facilitated by the provision of unglazed or partially glazed surfaces in contact with cement. In present-day designs, in place of the conventional form of insulator head, a smooth and unbroken glazed surface—especially in the design of cap-and-pin insulators—has been introduced. Other types which make use of the strengthening effect of the glazes on insulator bodies are the solid-core line and station post insulators, and the so-called motor and long-rod insulators which are used on the Continent to a very great extent as suspension and strain insulators.

FORTHCOMING EVENTS

Friday, January 1

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 2.30 p.m.—Miss Evelyn Cheesman: "Camps in New Guinea" (First Christmas Lecture).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ANALYTICAL CHEMIST to the City of York Electricity Department—The City Electrical Engineer, Electricity Offices, Clifford Street, York (endorsed 'Chemist') (December 31).

HEADMASTER of Felsted School—The Clerk to the Governors, Mr. Norman Orfeur, Solicitor, Braintree, Essex (December 31).

CHIEF LAND DRAINAGE OFFICER—The Executive Officer, Bucks War Agricultural Executive Committee, County Offices, Aylesbury, Bucks (Jan. 1).

LECTURER IN CHEMISTRY at the Brighton Technical College—The Education Officer, 54 Old Steine, Brighton, 1 (Jan. 8).

HEAD of the Engineering Department—The Principal and Clerk to the Governing Body, Wigan and District Mining and Technical College, Wigan (January 9).

LECTURER IN MECHANICAL ENGINEERING in the Oxford Schools of Technology, Art and Commerce—The Chief Education Officer, City Education Office, 77 George Street, Oxford (Jan. 17).

DIRECTOR of the National Froebel Foundation—The Secretary, National Froebel Foundation, 2 Manchester Square, London, W.1 (February 27).

CHAIR OF MINING—The Secretary, the University, Edmund Street Birmingham, 3 (March 1)

TWO CHEMISTS IN THE MINISTRY OF SUPPLY whose duties would be of an advisory, non-experimental nature—The Ministry of Labour and National Service, Central (Technical and Scientific) Register (Reference F.651), Sardinia Street, Kingsway, London, W.C.2.

REPORTS and other PUBLICATIONS

(not included in the monthly Books Supplement)

Great Britain and Ireland
